ABSTRACT

Background: This study examines the changes in segmental and global cervical sagittal parameters after single-level anterior cervical discectomy and fusion (ACDF) in patients with cervical radiculopathy or myelopathy. We also investigate whether these changes have any relation with postoperative pain and functional outcome of the patients.

Methods: Sixty patients (37 females and 23 males) with a mean age of 45.9 ± 9.5 years who were candidates of single-level ACDF due to cervical myelopathy or radiculopathy participated in the study. At baseline, 1 month, and 6 months after ACDF, outcomes of the study including sagittal balance parameters, pain intensity, and Neck Disability Index (NDI) were measured among the patients. Intensity of pain and neck disability were measured using the visual analog scale (VAS) and validated version of NDI, respectively. Using a standard lateral cervical radiography, the Cobb angle for occiput–C2, C1–C2, and C2–C7 as well as operation-level angle (OA; Cobb's angle at the level of discopathy), the thoracic inlet angle, and C7 and T1 slope angles were measured.

Results: The intensity of pain and neck disability of patients improved significantly during the follow up of the study comparing with baseline measurements ($P < .001$). There was a significant correlation between the increase of C2–C7 angle, C1–C2 angle, and OA and improvement in neck pain and NDI at 1- and 6-month follow ups.

Conclusions: We found that changes at C2–C7 angle, C1–C2 angle, and OA have positive significant correlation with clinical outcome including pain improvement and decrease of disability in patients who undergo ACDF.

Level of Evidence: 3.

Clinical Relevance: The results of this study might be beneficial in selection of cervical cages with appropriate size during ACDF surgery, as our findings showed that larger cages could lead to better functional outcome in patients.

Cervical Spine

Keywords: Cervical Discectomy, Sagittal balance, Disability, radiculopathy, Myelopathy

INTRODUCTION

Anterior cervical discectomy and fusion (ACDF) is the most common surgical procedure used for the treatment of patients with symptomatic cervical spondylosis and/or radiculopathy. There is growing evidence that sagittal parameters play a key role in determining the appropriate surgical approach in patients who undergo cervical surgery.^{1–3} Biomechanical studies have shown the effect of ACDF on

sagittal kyphosis and altered dynamics at levels adjacent to a cervical fusion.^{4,5} However, less interest is paid to the impact of single-level ACDF on the segmental and global cervical sagittal balance parameters and its relationship with functional outcome of the patients.

It was previously shown¹ that sagittal malalignment of the cervical spine, as measured by C2–C7 sagittal vertical angle (SVA) is related to unfavorable functional and health-related quality of life

outcomes. This poor outcome might be due to compensatory changes required to keep horizontal gaze and normal posture in patients with sagittal imbalance. In addition, authors⁶ demonstrated that single-level ACDF in patients with cervical myelopathy leads to increased upper cervical lordosis angle (C1–C2) with no significant effect on lower cervical lordosis (C2–C7). While others⁷ found that both global and segmental sagittal balance parameters improve significantly, after one- or multiple-level ACDF.

In this prospective study, we aimed to record the changes in segmental and global cervical sagittal parameters after single-level ACDF in patients with cervical radiculopathy or myelopathy and investigate whether these changes have any relation with postoperative pain (measured by visual analog scale [VAS]) and functional outcome (measured by Neck Disability Index [NDI]) of the patients. The findings of this study could help boost the efficiency of this procedure to get better functionality and quality of life in patients who undergo ACDF.

METHODS

Participants and Interventions

Included subjects were older than 18 years with no prior spinal surgery and no clinical spinal deformity with neck pain and/or radicular pain due to single-level discopathy at the level of C4–C5, C5–C6, or C6–C7. Patients' symptoms were resistant to conservative management, and all of them had a magnetic resonance imaging scan indicative of neural compression. The exclusion criteria were having a history of trauma and fracture in the spine; fibromyalgia and depression; inflammatory and neoplastic diseases; immune or metabolic diseases; any disease requiring chronic use of analgesics and nonsteroidal anti-inflammatory drugs; osteoporosis or diabetes mellitus; obesity (body mass index > 30); history of spinal surgery, pregnancy, upper motor neuron disease, or any other neuromuscular disorder; history of connective tissue disease; and complications of surgery (eg, infection at the site of surgery, cerebrospinal fluid leak). The process and aim of the study were described to the patients. All enrolled patients signed written informed consent. The study protocol was approved by the ethical committee of university.

The subjects underwent ACDF through right-sided approach and by a single surgeon.⁸ Anterior

cervical discectomy and fusion surgery was carried out under a microscopic guide using an interbody cage (Zimmer, Inc, Warsaw, IN) and allograft. No anterior plate was fixed for the patients. The patients received acetaminophen 500 mg as needed and ranitidine 150 mg b.i.d. for 7 days after surgery. Also, ondansetron was prescribed in case of nausea or vomiting in the first 24 hours after surgery. No analgesic drug was administered after day 7. The patients were discharged on the second postoperative day and were referred to our clinic 1 week later for wound care. Outcome measurements were done before surgery and 1 month and 6 months after surgery.

Outcomes

Preoperatively and 1 month and 6 months after surgery, all patients underwent lateral cervical spine x-ray study, and the cervical sagittal parameters of the subjects including C2–C7 angle, thoracic inlet angle, T1 slope, C7 slope, C1–C2 angle, craniocervical angle, occiput–C2 angle, and operation-level angle (OA; Cobb's angle at the level of discopathy), as well as C2–C7 SVA were measured (Figure 1). Lateral cervical radiographs were done in the clavicle position, which was previously described by Horton et al.⁹ The definition of each sagittal parameter was done according to previous publications.¹⁰ One

radiologic technologist performed all x-ray studies, and all subjects were positioned by the same physician at all follow ups. Radiographic measurements were all performed by 1 experienced author using a picture archiving and communication system.

At baseline, 1 month, and 6 months after surgery, the functional status and pain intensity of the subjects were measured using the NDI and VAS, respectively.

Statistical Analysis

Data analysis was performed with SPSS 16 (SPSS Inc, Chicago, IL). Data normality was assessed using the 1-sample Kolmogorov-Smirnov test. We computed the Pearson product-moment correlation coefficient to assess the relationship between changes in sagittal parameters and improvement in NDI and VAS at 1 month and 6 months after surgery. We also used a scatterplot to summarize the relationship between specific sagittal parameters and outcome measures.

RESULTS

In total, 70 patients were recruited in this study, but 10 subjects were excluded from the study due to

different reasons: 6 patients declined the calls for follow up, and 4 patients did not show up for follow ups. Finally, 60 patients with a mean age of 45.9 \pm 9.5 years were enrolled in the study and participated in 1- and 6-month follow ups. The demographic findings of the patients and their baseline measurements are shown in Table 1. The mean \pm SD of pain intensity of the patients was significantly decreased during 6-month (9.2 \pm 4.5) and 1-month (16.6 \pm 9.5) follow up of the study comparing with baseline (56.2 \pm 15.7) measurements ($P < .001$). Also, the mean \pm SD NDI of the patients improved significantly at 6-month (9.1 \pm 4.1) and 1-month (16.8 \pm 8.7) follow-up sessions comparing with preoperative (52.1 \pm 20.3) measurements ($P < .001$).

Sagittal Balance Parameters and Neck Pain and Disability

Correlation between sagittal balance parameter changes 1 month and 6 months after surgery in comparison with before surgery and improvement in disability and pain of patients are shown in Tables 2 and 3, respectively. There was a significant correlation between C2–C7 angle increase and improvement in the NDI at 1-month follow up, but this correlation did not last in 6-month follow up. However, the significant correlation between the increase of C1–C2 angle and OA and improvement in neck pain and NDI were found at 1- and 6-month follow ups. We used scatterplots to show the positive significant relationship between OA changes and improvement of neck pain and NDI at 1- and 6-month follow ups (Figure 2).

DISCUSSION

In this prospective study, we found that changes at C2–C7 angle, C1–C2 angle, and OA have positive

significant correlation with the clinical outcome including pain improvement and decrease of disability in patients who undergo ACDF. Overall, there are a few previous studies regarding the effect of lordosis and alteration of sagittal balance after single-level ACDF on clinical outcomes of patients. Our findings are consistent with the study by Villavicencio et al,¹¹ who reported improvement of functional outcome in patients with increase of segmental lordosis. Tang et al¹ also reported that improvement of cervical lordosis in patients who undergo posterior cervical laminectomy and fusion is related to better clinical outcomes in these patients. In contrast to these reports, Faldini et al¹² found no correlation between changes of sagittal parameters and functional outcome scores of patients after single-level ACDF. Spanos et al¹³ showed that the slight increase of mean cervical lordosis after ACDF was lost after 12-month follow up and had no significant correlation with pain and function of the subjects. Núñez-Pereira et al¹⁴ used C7 slope as an index of global sagittal balance in the cervical region and showed that there is no difference between C7 slope changes and function of patients after ACDF. Also, in a recent study, Lau et al¹⁵ reported on a series of patients who underwent from single-level to 3-level ACDF and plate fixation. They found that cervical lordosis, C2–C7 SVA, and T1 slope were not significantly associated with functional outcomes, specifically NDI and VAS scores of the patients. They assumed that normality of the radiologic measurements at baseline and minimal changes to the parameters after surgery were the possible reasons for this finding. Our results cannot be compared with this study due to different selection inclusion criteria and measurement angles.

According to our results (as shown in Tables 2 and 3), the OA showed the strongest positive correlation with clinical outcomes (including pain and functional disability) in patients after single-level ACDF. This finding is in parallel with the results of the study by Siasios et al,⁶ who showed that more lordotic segmental angles result in better functional outcome scores at the postoperative period. We assume that a possible explanation for this finding might be the role of ACDF on restoration of segmental slope at the operation level. This finding has been shown in the study by Zhang et al,⁷ as they found that global lordotic angle, segmental lordotic angle, and T1 slope were all improved after ACDF procedure and concluded that ACDF could be used to restore cervical sagittal alignment. Also, considering the recent study by Kim et al,¹⁶ who showed that ACDF can change not only regional but also the global sagittal parameters, the effect of ACDF on other sagittal parameters such as C1–C2 angle (which is responsible for more than half of cervical sagittal balance^{6,10,17,18}) could be explained. In fact, the interrelation between upper and lower cervical spine is complex. In case of C1–C2 kyphosis, the C2–C7 angle is hyperlordotic as a compensatory mechanism (downward sequential change), and therefore, when the upper kyphosis is corrected, the low cervical spine lordosis decreases. However, in the case of segmental kyphosis at the low cervical spine, the upward sequential change is more complicated, as an increase of the segmental lordosis at C5–C6 or C6–C7 after surgery might lead to a decrease of the adjacent upper lordosis (C2–C5 or C2–C6), which will lead to an increase of the C1–C2 angle.¹⁶ As it is shown in previous studies,^{10,16,19} compensatory mechanisms to try to keep horizontal gaze lead to alteration of cervical sagittal alignment in patients

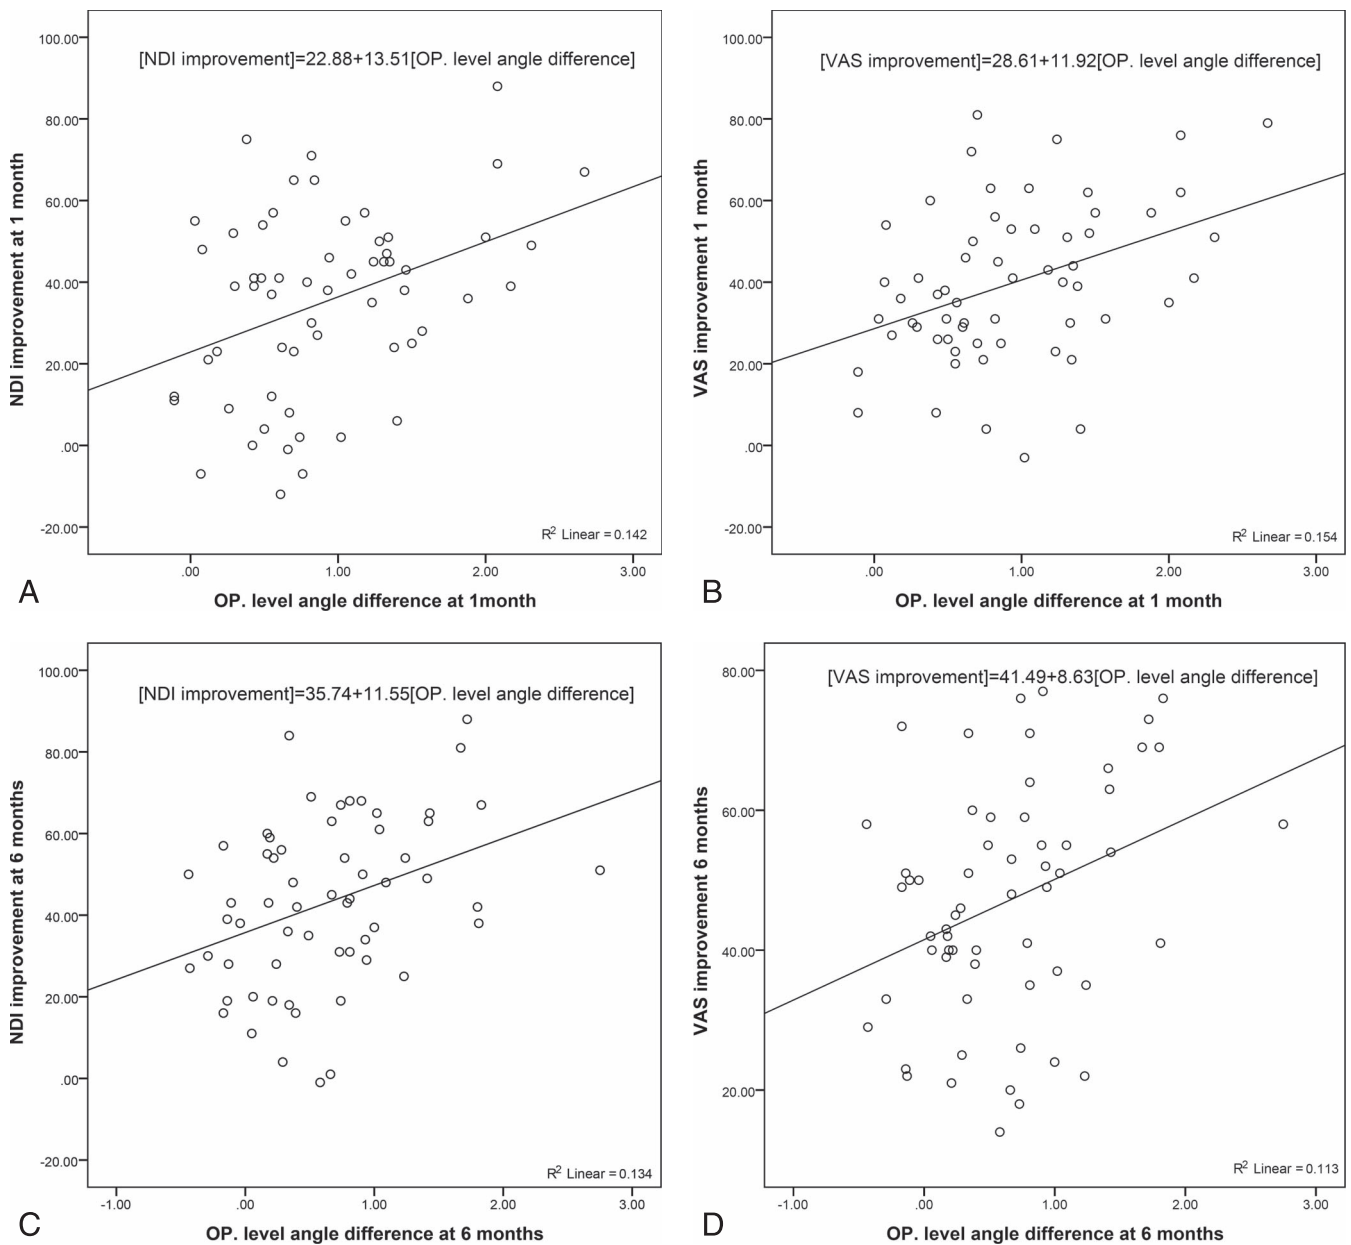

Figure 2. Relation of operation (OP) angle difference at 1 and 6 months and neck pain disability and pain improvement. (A) Relation of OP level angle difference and Neck Disability Index (NDI) improvement at 1 month. (B) Relation of OP level angle difference and visual analog scale (VAS) improvement at 1 month. with degenerative disc disease. Therefore, restoration of segmental lordosis (as shown by OA) and global cervical lordosis (as shown by increase of C1–C2 and C2–C7 angles) might be considered by every spine surgeon as an indicator to improve the functional outcome of patients.

Faldini et al¹² found that cervical lordosis improved 6 months after ACDF but decreased in long-term follow up (after 1 year). Godlewski et al²⁰ showed that, after ACDF, the greatest changes in lordosis and disk space height were noted immediately postsurgery. Baseline values were approximat-

ed gradually over time, but the postoperative values at 12 months were still higher than baseline, albeit this change was not correlated with clinical outcomes. In the current study, the patients were followed for only 6 months, and our findings cannot be compared with the Faldini et al¹² study. The short period of follow up should be considered as one of the limitations of this study. As another limitation, participants were not screened for level of physical activity, which might have a significant role in pain intensity and level of disability of the subjects.²¹ Also, we did not measure all the different

published angles for the study of the cervical spine sagittal alignment such as the occiput slope, the occiput–C1 angle, the angle between C2 and the upper vertebra included in the fusion, and also global sagittal parameters. There is evidence that anatomic change of sagittal balance in the cervical area is associated with compensatory changes in thoracic and even lumbar regions.^{22,23} However, in our study, this reciprocal effect was not identified since only cervical x rays were taken of the subjects.

CONCLUSIONS

In this study, we found that single-level ACDF leads to increase of upper and lower cervical lordosis (shown by C1–C2 and C2–C7 angles, respectively). The segmental lordosis at the level of operation (shown by OA) also significantly increased. There was a positive correlation between these parameters and the outcome of patients at 1 and 6 months. It seems that improvement of cervical lordosis has a significant role in improvement of functionality of the subjects. This needs to be further investigated in future studies.
