Abstract

Introduction

A novel expandable lumbar interbody fusion cage has been developed which allows for a broad endplate footprint similar to an anterior lumbar interbody fusion (ALIF); however, it is deployed from a minimally invasive transforaminal unilateral approach. The perceived benefit is a stable circumferential fusion from a single approach that maintains the anterior tension band of the anterior longitudinal ligament.

The purpose of this biomechanics laboratory study was to evaluate the biomechanical stability of an expandable lumbar interbody cage inserted using a transforaminal approach and deployed in situ compared to a traditional lumbar interbody cage inserted using an anterior approach (control device).

Methods

Twelve cadaveric spine specimens (L1-L5) were tested intact and after implantation of both the control and experimental devices in two (L2-L3 and L3-L4) segments of each specimen; the assignments of the control and experimental devices to these segments were alternated. Effect of supplemental pedicle screw-rod stabilization was also assessed. Moments were applied to the specimens in flexion-extension (FE), lateral bending (LB), and axial rotation (AR). The effect of physiologic preload on construct stability was evaluated in FE. Segmental motions were measured using an optoelectronic motion measurement system.

Results

The deployable expendable TLIF cage and control devices significantly reduced FE motion with and without compressive preload when compared to the intact condition (p<0.05). Segmental motions in LB and AR were also significantly reduced with both devices (p<0.05). Under no preload, the deployable expendable TLIF cage construct resulted in significantly smaller FE motion compared to the control cage construct (p<0.01). Under all other testing modes (FE under 400N preload, LB, and AR) the postoperative motions of the two constructs did not differ statistically (p>0.05). Adding bilateral pedicle screws resulted in further reduction of ROM for all loading modes compared to intact condition, with no statistical difference between the two constructs (p>0.05).

Conclusions

The ability of the deployable expendable interbody cage in reducing segmental motions was equivalent to the control cage when used as a stand-alone construct and also when supplemented with bilateral pedicle screw-rod instrumentation. The larger footprint of the fully deployed TLIF cage combined with preservation of the anterior soft-tissue tension band may provide a better biomechanical fusion environment by combining the advantages of the traditional ALIF and TLIF approaches.
out supplemental plate or pedicle screw fixation. Posterior lumbar interbody fusion (PLIF), transforaminal lumbar interbody fusion (TLIF), and anterior lumbar interbody fusion (ALIF) using interbody spacers (cages) and bone graft are some of the common forms of instrumented single-level lumbar fusion constructs for the treatment of painful degenerative disc disease with neurological compression.\textsuperscript{1-3}

Of these surgical options, ALIF implants are considered desirable due to improved visualization for endplate preparation and the relatively large implant footprint.\textsuperscript{4} TLIF and lateral interbody fusion have garnered recent interest due to their minimally invasive nature and improved segmental biomechanical stability.\textsuperscript{5-10} This stability is attributed to retention of the anterior and posterior longitudinal ligaments, annulus fibrosis, and the facet joints, as well as the large implant footprint when discussing lateral implants. Subsequent lumbar expandable interbody devices have been introduced to facilitate minimally invasive interbody fusion.\textsuperscript{11}

There is consensus in the literature that a greater degree of immobilization at the intended fusion levels confers a more ideal environment for boney fusion. Excessive motion interferes with the biologic process of bone healing and results in pseudarthrosis or nonunion.\textsuperscript{12,13} The mechanical environment conducive to promoting biologic fusion depends on the construct rigidity, which is defined as the ability of the fusion construct to limit intervertebral motion while the segment is subjected to physiologic forces and moments during activities of daily living. In the context of constructs that use interbody spacers such as cages, the construct rigidity, in turn, will depend on the footprint of the interbody cage. Secondly, a larger footprint of the interbody cage will distribute the forces going through the anterior column over a larger area of the vertebral endplates, thereby reducing the likelihood of subsidence while providing a larger space for bone graft placement.

The ALIF technique allows the use of an interbody cage with a larger footprint as compared to the traditional PLIF or TLIF cages; however, it requires resection of the anterior tension band (ALL and anterior annulus). TLIF cages can be implanted using a MIS techniques and allow for the retention of the anterior tension band. However, the small window between the exiting and traversing nerve roots limits the footprint size of the cage. Thus, a larger cage footprint and the necessity of disruption of the soft tissue tension band for cage insertion are two competing factors that influence the interbody cage construct rigidity. When posterior decompression surgery is required, the ability to place a cage with a large footprint through a posterior approach may provide an alternative to a “360” surgery necessitating an additional anterior surgical exposure.

The purpose of this study was to evaluate the biomechanical stability of a deployable and expandable lumbar interbody cage (Luna 360, Benvenue Medical, Inc., Santa Clara, CA) inserted through a transforaminal approach and deployed \textit{in situ} to a traditional lumbar interbody cage inserted using an anterior approach (“control” device). Both implants were tested in stand-alone constructs and with the addition of bilateral pedicle screws and rods.

\section*{Material and Methods}

\textbf{Specimens and Experimental Setup}

Twelve fresh frozen human cadaveric lumbar spine specimens (L1-L5) were used for this study (10 male, 2 female, age \(47.5 \pm 10.6\)). Radiographic screening was performed to exclude specimens with fractures, metastatic disease, bridging osteophytes, or other conditions that could affect the biomechanics of the spine. The specimens were thawed and dissected free of their paraspinal musculature while preserving the discs, facet joints, and osteoligamentous structures. The specimens were wrapped in saline soaked gauze to prevent dehydration of the soft tissues. All tests were performed at room temperature.

The specimens were fixed to the apparatus at the caudal-most vertebral body (L5) and were free to move in any plane at the cranial end (L1) (Figure 1). Bending moments were applied in flexion-extension and lateral bending by controlling the flow of water into bags attached to loading arms fixed to the L1 vertebra. In axial rotation, pure moment loading was applied by using two bags acting tangentially to a 30 cm diameter disc attached to L1. The apparatus allowed
continuous cycling of the specimen between specified maximum moment endpoints in flexion, extension, lateral bending, and axial rotation. The load-displacement data were collected until two reproducible load-displacement loops were obtained.

The angular motion of the L1 to L5 vertebrae were measured using an optoelectronic motion measurement system (Model Certus, Optotrak, Northern Digital, Waterloo, Ontario). In addition, bi-axial angle sensors (Model 902-45, Applied Geomechanics, Santa Cruz, CA) were mounted on each vertebra to allow real-time feedback for the optimization of the preload path. A six-component load cell (Model MC3A-6-1000, AMTI Multi-component transducers, AMTI Inc., Newton, MA) was placed under the specimen to measure the applied compressive preload and moments. Fluoroscopic imaging (GE OEC 9800 Plus digital fluoroscopy machine) was used to document intact disc heights and implant placement.

**Experimental Protocol**

Each specimen was tested in flexion (8 Nm) and extension (6 Nm) under 400 N of follower preload as well as without preload. Each specimen was also tested in lateral bending (±6 Nm) and axial rotation (±5 Nm) without preload. Specimens were tested under the following sequential conditions (Figure 2):

1. Intact spine
2. Stand-alone ALIF cage (at L3-L4 for specimens 1-6, at L2-L3 for specimens 7-12)
3. ALIF cage + Bilateral Pedicle Screws (at L3-L4 for specimens 1-6, at L2-L3 for specimens 7-12)
4. Stand-alone Luna TLIF cage inserted transforaminally and expanded in situ (at L2-L3 for specimens 1-6, at L3-L4 for specimens 7-12) (Figure 3)
5. Luna TLIF cage + Bilateral Pedicle Screws (at L2-L3 for specimens 1-6, at L3-L4 for specimens 7-12)

Thus, 12 segments were implanted with control ALIF cages; six at L2-L3 and six at L3-L4. Similarly, 12 segments were implanted with deployable and expandable cages; six at L2-L3 and six at L3-L4.

**Surgical Technique**

The ALIF “control” cage was implanted according to company surgical technique guidelines. A window matching the cage width was made in the anterior annulus and anterior longitudinal ligament. Disc mater-
was removed and the vertebral endplates were prepared in a conventional fashion while preserving their mechanical integrity. Trial sizing aided by fluoroscopy was performed to select the proper cage size.

Implantation of a deployable and expandable lumbar interbody fusion device (Luna 360, Benvenue Medical, Inc., Santa Clara, CA), was performed using the standard transforaminal approach. A small window was made in the posterolateral annulus. Disc material was removed to allow sufficient room for the device to be deployed. The device was then deployed in situ to produce its axial footprint, and finally expanded, effectively distracting the intervertebral disc space (Figure 4). Once deployed, the implant presents a graft window that allows bone graft material to be inserted post-expansion; however, no bone graft material was utilized for this biomechanical assessment.

**Statistical Analysis**

The applied moment versus vertebral motion data were analyzed using standard methods of rigid body kinematics. Segmental ranges of motion values were analyzed using paired-sample t-tests. The following comparisons were made:

1. Combined control cage (n=12) vs Combined deployable and expandable cage (n=12)
2. Combined control cage + PS (n=12) vs Combined deployable and expandable cage + PS (n=12).

These comparisons were done separately for flexion-extension, lateral bending, and axial rotation, since no comparisons across load-types were intended in the study design. The statistical data analyses performed with use of the Systat 10.2 software package (Systat Software, Richmond, CA).

**Results**

When used as a stand-alone device, the deployable and expandable TLIF cage significantly reduced motion in flexion-extension, from 7.1 ± 1.1 degrees to 3.3 ± 1.3 degrees under no preload, p<0.01, and from 7.1 ± 1.1 degrees to 3.1 ±1.1 degrees under 400N preload, p<0.01 (Table 1). This represents a decrease in sagittal plane motion by 53% and 57%, respectively. The control cage also significantly reduced flexion-extension, lateral bending, and axial rotation, since no comparisons across load-types were intended in the study design. The statistical data analyses performed with use of the Systat 10.2 software package (Systat Software, Richmond, CA).
extension motion, from 7.4 ± 1.8 degrees to 5.2 ± 1.4 degrees under no preload, p<0.01, and from 7.4 ± 1.6 degrees to 2.9 ± 0.8 degrees under 400N preload, p<0.01 (Table 2). This represents a decrease in sagittal plane motion by 28% and 61%, respectively (Figure 5, Figure 6). The difference in the abilities of the deployable and expandable cages and control devices in limiting flexion-extension motion under the preload of 400N was statistically equivalent (57% vs. 61%, p=0.31). However, in the absence of compressive preload, the deployable and expandable TLIF cage was superior in limiting flexion-extension motion (53% vs. 28%, p=0.00).

In lateral bending, the deployable and expandable TLIF cage reduced motion from 8.0 ± 1.5 degrees to 4.1 ± 1.5 degrees, p<0.01. This represents a decrease in coronal plane motion of 50%. The control cage reduced motion from 8.9 ± 1.9 degrees to 3.9 ± 1.7 degrees, p<0.01. This represents a reduction of coronal plane motion of 56.4% (Table 1 & Table 2, Figure 7). There was no statistically significant difference in the abilities of the deployable and expandable cages and control devises in limiting lateral bending motion (50% vs. 56%, p=0.26).

In axial rotation, the deployable and expandable TLIF cage reduced range of motion from 2.4 ± 1.4 degrees to 1.5 ± 0.5 degrees, p<0.05. This represents reduced motion in the axial plane by 21%. The ALIF control cage reduced motion from 2.6 ± 2.1 to 1.6 ±0.9 degrees, p<0.05. This represents reduced motion in the axial plane of 22% (Table 1 & Table 2, Figure 8). The difference in the abilities of the deployable and expandable cages and control devices in limiting axial rotation motion was statistically equivalent (21% vs. 22%, p=0.94).

Supplemental posterior fixation using bilateral pedicle screws and rods resulted in further reduction in ROM in flexion-extension, lateral bending, and axial rotation (Table 1 & Table 2). The effect of supplemental fixation was significant compared to the stand-alone devices, for both TLIF and ALIF cages (p<0.01). Both devices, when used in conjunction with supplemental fixation, were statistically equivalent in their ability to reduce segmental motion in flexion-extension (p>0.22), lateral bending (p=0.06), and axial rotation (p=0.61).

Discussion

This study compared the relative biomechanical stability between two implants of similar footprint size inserted using two different surgical approaches. The shape and size of the fully deployed and expandable TLIF cage is very similar to a traditional ALIF cage. Despite the fact that the anterior longitudinal ligament is removed during ALIF insertion, we chose not to compare to a traditional TLIF cage since the endplate coverage is much smaller than the deployable and expandable Luna cage. Therefore, both deployable and expandable TLIF cage and ALIF cages provide similar surface area for bone graft material, increased stiffness imparted by anterior column support, and the ability to restore sagittal alignment.

Lumbar interbody fusion utilizing a fusion cage with bone graft has benefits when compared to a posterolateral fusion technique. The benefits include greater surface area for bone graft-endplate interface, increased stiffness due to anterior column support, and the ability to restore alignment. Circumferential constructs consisting of an anterior cage and posterior instrumentation has been shown to improve fusion rates. A number of interbody technique have been described including ALIF, PLIF and TLIF; each with its own respective advantages and disadvantages. Prior interbody fusion techniques when used in circumferential fusions have the advantage of a single approach. However, the anatomy limits the size of the interbody device that can be inserted posteriorly. The anterior approach affords a larger implant footprint given the unencumbered path to the disk space. Grant and colleagues demonstrated that lumbar endplate density and cortical thickness increase as one approaches the periphery of the vertebral body which makes placement of a cage with larger surface area desirable.

A deployable and expandable lumbar interbody fusion cage which allows for a single, minimally invasive, posterior approach and annulotomy with intervertebral deployment resulting in a broad-based footprint may improve outcomes and limit complication. The purpose of this study was to demonstrate biomechanical equivalency of this type of a device to a standard ALIF cage. The biomechanical stability of the deployable and expandable TLIF cage was found to be at least equivalent to the ALIF cage, both when used as stand-alone devices as well as when supplemented with bilateral pedicle screw-rod stabilization. Although neither implant is intended to be used as a stand-alone device, both implant types were tested as such in order to elucidate the stability imparted by the interbody device itself, independent of the posterior instrumentation. The in situ expandable nature of the cage after implantation allows for distraction.
of the disc space without violating endplates during insertion for the same cage size.

The two devices significantly reduced segmental motion at the level of implantation and no statistical difference between the devices in reducing flexion-extension with compressive preload, lateral bending, or axial rotation was observed. Under flexion-extension testing without preload, there was a statistically significant difference between the two devices favoring increased stability of the deployable and expandable TLIF cage. This is attributable to the retention of the anterior tension band and a small annular window of the TLIF approach through which the deployable and expandable device can be inserted prior to in situ expansion.

The compressive preload in the lumbar spine is caused by the action of muscles and has been shown to vary from a low value of 200 N during supine and lateral recumbent postures to over 1000 N during standing and walking. Therefore, the improved stability of the stand-alone deployable and expandable TLIF cage construct, compared to the stand-alone ALIF cage construct in the absence of a compressive preload may offer improved protection against migration during the low preload activities.

**Limitations**

As any cadaveric biomechanical investigation, our study has limitations. We compensated for the absence of active muscles by using follower preload (6-9). In this study our implantation levels of L2-L3 and L3-L4 were chosen in order to have similar anatomy (wedge angle, facet angulation) and kinematics at the two implanted levels. Utilizing L4-L5 would have been more clinically relevant but the lordosis and range of motion at L4-L5 is significantly different than at L3-L4.

**Conclusions**

The deployable and expandable Luna cage that can be inserted through TLIF approach with a small annular window and expanded axially in situ has the advantages of a single posterior approach and broad endplate footprint while retaining the anterior tension band for added stability. When compared to an ALIF cage, the deployable and expandable TLIF cage demonstrates biomechanical equivalence in regards to segmental stability in the coronal, sagittal, and axial planes. The effect of this on fusion rate and decreased complications needs to be clinically studied.

The deployable and expandable TLIF cage is an improvement over traditional fixed dimension TLIF cages due to the implant’s deployment technology making implantation possible through a narrow surgical corridor resulting in minimal nerve root retraction and tissue dissection. Additional benefits over traditional TLIF designs include a much larger endplate footprint and the ability to axially expand the device to add annular tension and segmental lordosis.
