ABSTRACT

Background: In the presence of chin-on-chest deformity of ankylosing spondylitis, positioning for extension osteotomy of the spine is a challenging endeavor. Conventional prone positioning equipment cannot safely accommodate all patients with advanced deformity where the chin brow angle approaches or exceeds 90°. Issues such as inability to accommodate the head and associated equipment while providing operative stability and venous congestion of the head represent significant perioperative risks. The sitting position has been advocated as an alternative but is suboptimal for surgical access and anesthetic care. We present a technical note for a positioning system developed to facilitate extension osteotomy in the prone position.

Methods: A positioning device was designed to accommodate patients with advanced deformity. A series of patients with chin brow angles of up to 89° were positioned using our new system.

Results: We were able to facilitate safe extension osteotomy in the prone position, for procedures lasting up to 14 hours. All our patients were discharged home without significant complication.

Conclusions: Our device is simply constructed and may be easily replicated in other institutions engaging in complex spine surgery. We hope our system provides clinicians with greater freedom to provide optimal perioperative care to their patients.

New Technology

Keywords: prone positioning, vertebral

INTRODUCTION

Ankylosing spondylitis is a progressive inflammatory joint disease associated with major sequelae including fixed ankylosis of the thoracic and cervical spine. Deformity of the thoracic cavity affects cardiorespiratory function and loss of sagittal balance along with inability to visualize the horizon impairs ambulation. Physiological impairment and functional limitation compound one another, leading to frailty, reduced quality of life, and reduced life expectancy.¹ Disabling pain is common as well as malnutrition due to difficulty with chewing and swallowing.

Severe deformity often mandates surgical correction. Extension osteotomy of the cervical and thoracic spine was originally performed without general anesthesia in the sitting or lateral position.^{2,3} The primary mode of anesthesia was local infiltration, supplemented by inhaled nitrous oxide or intravenous barbiturate, administered at the time of

instrumentation. The major determinant of this choice was cited as challenging perioperative care, including anticipated difficult intubation. Advancements such as fiberoptic intubation and neurophysiological monitoring have increased safety; however, use of the sitting position has survived these innovations.⁴

The sitting position is suboptimal for surgical access and anesthetic care.⁵ Osteotomy in the prone position was introduced, and accounts have been offered of general anesthesia for chin-on-chest deformity.^{6–12} The use of foam blocks, bolsters, or pillows to support the patient has been described. Where the chin-brow angle approaches 90° and is fixed, these means are not able to safely elevate the patient above the operating table without dangerous instability or obstruction of the abdomen.

Use of a Jackson table has been described to accommodate the head in chin-on-chest deformity.⁷

Figure 1. Critical issue with conventional positioning equipment. (A) Venous congestion due to fixed position of the head. (B) Reverse Trendelenburg capability of standard operating table insufficient to mitigate congestion.

We engage in a process of awake trial positioning for our most challenging patients. We discovered that, in advanced presentations, a critical issue arises due to the relative position of the venous drainage of the head and right atrium (Figure 1). Due to the prolonged nature of the requisite procedures, venous congestion may result in cerebral edema, airway edema, and visual loss.^{13–15} The steep reverse Trendelenburg orientation required to overcome this issue is not possible with a Jackson table, precluding the use of this option for our patients.

All commercially available prone positioning systems were considered, and options were trialed, such as an Allen® Advance table and Relton-Hall blocks in standard configuration and augmented using high-density polyurethane foam and operating table attachments. Lack of stability, inability to accommodate the Mayfield® clamp, and venous congestion prohibited the use of any such system. We were faced with a significant positioning conundrum demanding a creative solution.

We offer a technical report for a positioning system using the Advanced Deformity Adjustable Prone Positioning Tool (ADAPT; Figure 2). The presenting morphology of our patients positioned to date is illustrated in Figure 3A.

MATERIALS AND METHOD

Positioning System

A 3-dimensional, topographical reconstruction of our first patient was produced using infrared imaging and used to model a new positioning device (Figure 4A). The ADAPT was developed to work in conjunction with a standard operating table, augmenting reverse Trendelenburg capability (in our institution: Eschmann T20, 35°/Maquet Alphamaxx, 30°). It was designed to provide stable operating conditions and to accommodate the head, ventilating circuit, and Mayfield frame.

The device is assembled from a set of interchangeable components and may accommodate a range of needs. It consists of a polyethylene foam body and a rigid acrylonitrile butadiene styrene plastic top. Relton-Hall supports, attached by hook and loop fastenings, are used to bridge the device and the patient's thorax and pelvis (Figure 4B).

A top component with a cutout section enabled the head to be accommodated in its fixed position. We encountered a patient with less advanced deformity that could be positioned without a cutout, but who still required use of the ADAPT to mitigate venous congestion. We found a top component without a cutout useful in this circumstance, enabling greater versatility in placement of Relton-

Hall supports. Smaller foam wedges were used to provide additional inclination where necessary, attached to the main body of the device by hook-and-loop fastenings. The greatest overall reverse Trendelenburg incline that we have required to date was 50°.

The body of the device was produced by computer numerical control milling. High-density medical grade polyethylene foam was used due to its favorable physical properties. It is inexpensive, lightweight, resistant to damage, and the overall shape does not deform under the weight of a patient over time, providing operative stability. The rigid top was vacuum formed from heat moldable thermoplastic and fit securely over the top of the polyethylene block.

At inclines of the magnitude required for our patients, instability was anticipated because of gravity. In addition to Relton-Hall supports, the knees were immobilized by gel and foam supports. A final point of contact ensured stability via a Tarlov seat applied to the patient posteriorly, which was in turn supported by a strap attached under tension to the operating table. After a successful trial positioning episode, with our patient providing

feedback regarding comfort and stability, we were able to proceed confidently with this configuration.

A side effect of the steep inclination was that the surgical field was significantly elevated above ground level. A raised platform was available to ensure we could provide comfortable operating conditions for surgeons and scrub staff if necessary.

Positioning Technique

Prone positioning was performed by an experienced team consisting of 5 or more members, directed by the anesthesiologist in control of the head and airway. An appropriate positioning system configuration was determined during a preoperative visit.

The system was assembled on the operating table with the ADAPT and lower limb supports securely attached by 100-mm Slek® waterproof adhesive tape. The position of the Relton-Hall chest and pelvis supports was finalized before prone positioning, with the patient anaesthetized in the supine position. The operating table was oriented with Trendelenburg tilt to align the blocks with the patient, in the supine position. The patient was positioned adjacent to the operating table with the chest and anterior superior iliac spines in line with

Figure 3. Patients' (A) preoperative and (B) postoperative spines.

Figure 5. Positioning system configuration. (A) Patient positioned prone on positioning equipment. (B) Schematic illustration: (i) Mayfield frame, (ii) ADAPT device, (iii) Relton-Hall supports, (iv) Tarlov seat, (v) supporting strap, and (vi) gel and foam support to protect and immobilize knees.

the supports. Meticulous care was taken before prone positioning to ensure the provision of ample space to accommodate the fixed flexion deformity of the head and neck.

The patient was maneuvered onto the equipment in a logrolling fashion. The head was secured via a Mayfield clamp (applied before proning) or with a ProneView® device. Monitoring and invasive devices were checked and systemic stability ensured before minor adjustments of position were performed to free abdominal excursion. The arms were secured according to surgical requirements, either by the patient's side or above the head. Pressure areas were assessed, with particular attention to ventral weight-bearing areas, and protected with gel pads and foam. A Tarlov seat and supporting strap were applied to support the patient posteriorly.

With positing finalized, reverse Trendelenburg orientation was used to relieve venous congestion of the head and provide optimal surgical access (Figure 5B). During this process, care was taken to ensure stability, particularly with respect to prevention of caudal migration of the patient down the operating table. After meeting these prerequisites, the operations could proceed safely.

RESULTS

Details of our patients' backgrounds, their operative procedures, and outcomes can be found in the Table. Figure 5A illustrates our patient still positioned prone after successful correction of a severe chin-on-chest deformity. We have used the system described to safely facilitate surgery for 4

patients, with a maximum preoperative chin-brow angle of 89°. Prone positioning was safely used for a duration of up to 14 hours.

We encountered 1 instance of grade 1 pressure injury of the skin, assessed according to National Pressure Ulcer Advisory Panel criteria.¹⁶ In another case, an episode of postoperative ventilation was required due to airway edema.

Safe care was achieved in each case, with marked improvement in the postoperative chin-brow angle (Figure 3B). All patients were fit for discharge after a routine postoperative course, unaffected by complications.

DISCUSSION

Complications and Limitations

Prone positioning is associated with various physiological issues and complications that are well documented.^{13–15} Our position, with its unusual spatial orientation, may be subject to limitations which are not yet apparent. We consider these potential problems in the context of evidence relating to the well-established prone and jack knife positions, which are most similar.

Incidence of pressure injury of the skin in spinal surgery patients positioned prone has been cited as 23%.¹⁷ The problem is commonly encountered in such patients, and we could not identify any characteristics of our system that may have contributed to the problem beyond the risk for conventional prone positioning methods.

Prolonged prone positioning is associated with airway edema, and venous congestion of the head

Table. Patient medical histories, procedures, and outcomes.

Demographics	Past History	Presentation	Procedure	Positional Injuries	Outcome
56, Male	Ankylosing spondylitis Cervical spine fracture NIDDM Smoker Paroxysmal palpitations Astrocytoma 1970 Poor exercise tolerance BMI = 36.5	Cervical ankylosis No neurology Chin-brow angle = 89°	Posterior cervical osteotomy C2–T6 instrumentation 12 h prone	Grade 1 pressure injury— chest, shoulder, anterior superior iliac spine	Chin-brow angle = 39° Discharged 10 d
53, Male	Ankylosing spondylitis Bilateral hip replacements Good exercise tolerance BMI = 26.2	Cervical and lumbar ankylosis Chin-brow angle = 27°	(a) Posterior L4–5 osteotomy L1–S1 and Iliac instrumentation 14 h prone (b) Posterior cervical osteotomy C2–T5 instrumentation 11 h prone	Airway edema requiring surgical tracheostomy	Chin-brow angle = unknown Lost to follow up Discharged 43 d (inpatient until second operation)
60, Male	Ankylosing spondylitis Multiple sclerosis (relapsing remitting) Good exercise tolerance BMI = 28.3	Thoracolumbar ankylosis Chin-brow angle = 39°	Circumferential lumbar osteotomy Posterior L1–S1 and Iliac instrumentation 12 h prone	None	Discharged 8 d Chin-brow angle = 12°
55, Male	Ankylosing spondylitis Diffuse idiopathic skeletal hyperostosis Previous DVT Pernicious anemia Gastric band Significant chronic pain issues Thoracolumbar fixation (2013) Wheelchair bound BMI = 35.6	Cervicothoracic ankylosis Chin-brow angle = 37°	Posterior cervical osteotomy C3–T5 instrumentation 8 h prone	None	Discharged 19 d Chin-brow angle = 8°

Abbreviations: BMI, body mass index; DVT, deep vein thrombosis; NIDDM, non-insulin dependent diabetes mellitus.

contributes to the problem. Observation of the patient's skin throughout the procedure enabled us to ensure that the incline of our position was adequate to mitigate this problem. The incidence of airway edema despite our precautions serves to illustrate the importance of the vigilance in this respect.

Complex osteotomy of the spine is associated with potential for significant blood loss, causing cardiovascular and hematological disturbances. Prone positioning may compound this effect as it is associated with a significant decrease in cardiac index, and the steep incline of our position may be disadvantageous in this sense.^{18,19} We did not encounter any problems of this nature.

Improved lung mechanics are associated with the prone position. However, compliance decreases with an associated increase in ventilating pressures.²⁰ This was noted in our patients, although the clinical significance may be limited, and the steep incline may serve to mitigate the effect.²¹

Due to the steep incline and duration of prone positioning, we were mindful of the potential for

compartment syndrome. We assessed capillary refill time and skin color of the lower limbs and planned to intermittently level the patient if these findings suggested the incidence of congestion.

Venous air embolism was also a concern, given the steep incline of our position. We considered the risk of this problem comparable to other conventional positioning methods in which there is a significant difference in height between the head and right atrium.

Practical Considerations

To accommodate the fixed position of the head, our patients were significantly elevated above the operating table. This may be problematic when the total width between the operative site and the underside of the table exceeds the capacity of the C-arm of the intraoperative image intensifier. We did not encounter this issue, having used trial positioning to verify compatibility of the equipment.

Caudal migration down the operating table was noted during trial positioning. Where the head is secured in a Mayfield clamp, this constitutes a

significant risk. Once identified, we were able to verify that the patient's knees were securely immobilized, and we did not encounter any problems with movement after this.

We acknowledge the limitation of the current sample size and plan to carry out a more extensive investigation into the use of our system once the data become available.

CONCLUSIONS

We present a system which enables patients with severe chin-on-chest deformity to undergo osteotomy in the prone position, facilitating optimal surgical access and safe perioperative care. The ADAPT is simply constructed and may be easily and economically replicated. Where the sitting position is still employed for complex spine surgery, we hope that our system empowers surgeons and anesthesiologists with greater freedom to provide optimal perioperative conditions for their patients suffering from advanced deformity.
