Abstract

Background

Cervical total disc replacement (TDR) is an increasingly accepted procedure for the treatment of symptomatic cervical degenerative disc disease. Multiple Level I evidence clinical trials have established cervical TDR to be a safe and effective procedure in the short-term. The objective of this study is to provide a long-term assessment of TDR versus anterior discectomy and fusion for the treatment of one- and two-level disc disease.

Methods

This study was a continuation of a prospective, multicenter, randomized, US FDA IDE clinical trial comparing cervical TDR with the Mobi-C® Cervical Disc versus ACDF through 7 years follow-up. Inclusion criteria included a diagnosis of symptomatic cervical degenerative disc disease at one or two cervical levels. TDR patients were treated using a Mobi-C® artificial disc (Zimmer Biomet, Austin TX, USA). ACDF with allograft and anterior plate was used as a control treatment. Outcome measures were collected preoperatively and postoperatively at 6 weeks, at 3, 6, 12, 18 months, annually through 60 months, and at 84 months. Measured outcomes included Overall success, Neck Disability Index (NDI), VAS neck and arm pain, segmental range of motion (ROM), patient satisfaction, SF-12 MCS/PCS, major complications, and subsequent surgery rate. The primary endpoint was an FDA composite definition of success comprising clinical improvement and an absence of major complications and secondary surgery events.

Results

A total of 599 patients were enrolled and treated, with 164 treated with one-level TDR, 225 treated with two-level TDR, 81 treated with one-level ACDF, and 105 treated with two-level ACDF. At seven years, follow-up rates ranged from 73.5% to 84.4% (overall 80.2%).

The overall success rates of two level TDR and ACDF patients were 60.8% and 34.2%, respectively ($p < 0.0001$). The overall success rates of one level TDR and ACDF patients were 55.2% and 50%, respectively ($p > 0.05$). Both the single and two level TDR and ACDF groups showed significant improvement from baseline NDI scores, VAS neck and arm pain scores, and SF-12 MCS/PCS scores ($p < 0.0001$). In the single level cohort, there was an increased percentage of TDR patients who reported themselves as “very satisfied” (TDR 90.9% vs ACDF 77.8%; $p = 0.028$). There was a lower rate of adjacent level secondary surgery in the single level TDR patients (3.7%) versus the ACDF patients (13.6%; $p = 0.007$).

In the two level TDR group, the NDI success rate was significantly greater in the TDR group (TDR: 79.0% vs. ACDF: 58.0%; $p = 0.001$). There was significantly more improvement in NDI change score at 7 years in the TDR patients versus ACDF. The TDR group had a significantly higher rate of patients who were “very satisfied” with their treatment compared to the ACDF group (TDR: 85.9% vs. ACDF: 73.9%). The rate of subsequent surgery at the index level was significantly lower in the TDR group compared to the ACDF group (TDR: 4.4% vs. ACDF:

16.2%; $p=0.001$). The rate of adjacent level secondary surgery was significantly lower in the two level TDR (4.4%) patients compared to the ACDF (11.3%; $p=0.03$) patients. In both single and two level cohorts, the percentage of patients with worse NDI (2.5%-3.8% of two level surgeries and 1.2%-2.5% of single level surgeries) or worse neck pain (5%-6.8% of the two level surgeries and 1.3% - 3.8% of the single level surgeries) was strikingly low in both groups but trended lower in the TDR patients.

Conclusions

At seven years, the composite success analysis demonstrated clinical superiority of two level TDR over ACDF and non-inferiority of single level TDR versus ACDF. There were lower rates of secondary surgery and higher adjacent level disc survivorship in both groups. Both surgeries were remarkably effective in alleviating pain relative to baseline and the rate of patients with worse disability or neck pain was surprisingly low. Overall, greater than 95% of patients (from both groups) who underwent TDR and 88% of patients who underwent ACDF were “very satisfied” at seven years. The differences in clinical effectiveness of TDR versus ACDF becomes more apparent as treatment increases from one to two levels, indicating a significant benefit for TDR over ACDF for two-level procedures.

Ethical Standards

The Mobi-C Clinical Trial (ClinicalTrials.gov registration number: NCT00389597) was conducted at 24 sites in the US and was approved by the Institutional Review Board, Research Ethics Committee, or local equivalent of each participating site.

PAGES 244 - 262

Introduction

Neck and arm pain have shown to negatively impact multiple facets of patient health¹ and neck pain alone remains one of the largest contributors to the overall global health burden.² Since the mid-20th Century, the standard surgical procedure for treating symptomatic cervical spondylosis has been anterior discectomy and fusion (ACDF). While ACDF is a highly effective procedure, there are two major, procedure-specific complications: pseudoarthrosis and adjacent segment degeneration (ASD).³

The causative relationship between ACDF and ASD most likely lies in the kinematics and functionality of the partially fused spine. As motion in treated segments is eliminated through fusion, adjacent segments become hypermobile and adjacent discs experience increased loads and stresses.⁴⁻⁷ In turn, these kinematic changes have the potential to initiate or accelerate pathologies in intact segments. Unfortunately, the immobility of treated segments is the very nature of the fusion procedure, required for stabiliza-

tion after discectomy. As such, it seems only natural to seek an alternative surgical technique in which natural, healthy motion is preserved or restored.

Cervical total disc replacement (TDR) was developed in an effort to preserve natural spinal kinematics while providing mechanical stabilization after neural decompression and discectomy. Several Level I evidence randomized clinical trials have confirmed both the safety and efficacy of TDR in both the short- and long-term.⁸⁻¹⁴ TDR has shown to have many possible advantages over ACDF including lower rates of subsequent surgical intervention,^{15,16} lower rates of adjacent segment degeneration,^{13,17,18} and an advantage in cost-effectiveness.^{19,20} Furthermore, kinematic analyses have shown TDR to maintain functional biomechanics at the level treated while mitigating excess motion at adjacent segments.²¹

The purpose of this study is to expand on results from the Mobi-C® Cervical Disc FDA IDE clinical trial with 7-year data. Previously reported 2-^{13,22}, 4-^{14,23}, and 5-year^{24,25} follow-up results from this ran-

domized clinical trial have shown equivalent or better performance of TDR compared to ACDF at both one and two levels of treatment. Here, we present 7-year results from the one and two level arms for a comprehensive, long-term evaluation of TDR with Mobi-C®.

Methods

Study Design and Patient Population

The study was a prospective, randomized multicenter clinical trial conducted at 24 sites in the US. The study was divided into two separate arms of one-level and two-level treatment, conducted in tandem. Enrollment criteria included a diagnosis of degenerative disc disease with radiculopathy or myeloradiculopathy at either one or two contiguous levels from C3 to C7. General inclusion and exclusion criteria are listed in Table 1.

Patients were randomized in a 2:1 ratio (investigational: control) and received surgery between April 2006 and March 2008. The investigational group was treated with TDR using the Mobi-C® Cervical Disc (Mobi-C, Zimmer Biomet, Austin, TX, USA) (Figure 1). The control group received ACDF with allograft and anterior plate. A total of 164 patients were treated with one-level TDR, 81 with one-level ACDF, 225 with two-level TDR, and 105 with two-level ACDF. Surgeons were blinded up to the time of the procedure and patients were blinded until after surgery. Blinding afterwards was not possible due to differences in postoperative recovery protocols and the ability for patients to view their own radiographs.

Postoperative recovery schemes were left to the discretion of the treating surgeons. All patients were instructed to refrain from taking non-steroidal anti-inflammatory drugs (NSAIDs) a week before surgery until 3 months post-surgery. Patients were followed at 6 weeks, 3 months, 6 months, annually to 5 years, and then again at 7 years. A detailed description of the study design, including surgical technique, has been previously published by Davis et al (2013).¹³ A CONSORT diagram is included in the Appendix.

Outcome Measures

Patient reported clinical outcomes included the neck

disability index (NDI), the visual analog scale (VAS) for neck and arm pain, the short-form 12-item questionnaire (SF-12) for physical health (PCS) and mental health (MCS), and a patient satisfaction survey. For VAS arm pain, the mean improvement from baseline is reported for the most symptomatic arm at preoperative. In the event that a patient had equal preoperative VAS arm pains scores, the improvement in both arms was taken as the average improvement of both arms. To account for differences at presentation between patients and facilitate explanation

Table 1. Study Inclusion and Exclusion Criteria.

Inclusion Criteria
<ul style="list-style-type: none"> • Age 18-69 years; • Symptomatic cervical degenerative disc disease in one or two levels between C3-C7 with: <ul style="list-style-type: none"> ◦ Myelopathy or myeloradiculopathy and/or ◦ Decreased muscle strength and/or ◦ Abnormal sensation and/or abnormal reflexes; • Deficit confirmed by CT, MRI, or X-ray; • NDI Score of $\geq 30/100$; • Unresponsive to non-operative treatment for at least 6 weeks or presence of progressive symptoms or signs of nerve root/spinal cord compression despite continued non-operative treatment; • No prior surgical procedures at the operative level and no prior fusions at any cervical level; • Physically and mentally able and willing to comply with the protocol; • Signed informed consent; • Willingness to discontinue all use of non-steroidal anti-inflammatory drugs (NSAIDs) from one week before surgery until 3 months after surgery;
Exclusion Criteria
<ul style="list-style-type: none"> • More than two vertebral levels requiring treatment; • Immobile levels between C1 and C7 from any cause; • Any prior surgery at the operative level or any prior fusion at any cervical level; • Disc height less than 3 mm; • T-score less than -1.5 (osteoporosis evaluation); • Paget's disease, osteomalacia, or any other metabolic bone disease other than osteoporosis; • Active infection of surgical site or history of or anticipated treatment for systemic infection including HIV and/or Hepatitis C; • Active malignancy: a history of any invasive malignancy (except non-melanoma skin cancer), unless treated with curative intent with no clinical signs or symptoms of malignancy in the past 5 years; • Marked instability of the cervical spine on resting lateral or flexion-extension radiographs; • Known allergy to device materials including cobalt, chromium, molybdenum, or polyethylene; • Segmental kyphosis of greater than 11° at treatment or adjacent levels; • Rheumatoid arthritis, lupus, or other autoimmune disease; • Any diseases or conditions that would preclude accurate clinical evaluation; • Daily, high-dose oral and/or inhaled steroids or a history of chronic use of high dose steroids; • Morbid obesity (BMI > 40); • Use of any other investigational drug or medical device within 30 days prior to surgery; • Pending litigation relating to spinal injury (worker's compensation not included); • Smoking more than one pack of cigarettes per day; • Reported to have a mental illness or belonging to a vulnerable population.

of the data to non-spine providers, recovery ratios (RR) were calculated as the percentage difference between pre- and post-operative scores using the method of Hirabayashi:²⁶

$$RR = ([\text{Follow-up score}] - [\text{Baseline score}]) / ([\text{Optimum score}] - [\text{Baseline score}])$$

where optimum score is the best possible score for that outcome measure (e.g. 0 for VAS, 100 for SF-12). The recovery ratio represents the improvement in outcome normalized to the patient's baseline outcome score relative to the possible improvement in outcome.

Patients were asked two questions related to satisfaction. For patient satisfaction, patients were surveyed if they were "very satisfied," "somewhat satisfied," "somewhat dissatisfied," or "very dissatisfied" with their treatment. Patients were also asked how likely they were to recommend their respective surgery to a friend with possible responses of "definitely," "probably," "probably not," and "definitely not." For the purposes of this investigation, high likelihood to recommend was calculated as the proportion of patients who answered "definitely yes" or "probably yes" for the questionnaire.

Radiographic outcomes included measurements of flexion-extension and lateral bending range of motion (ROM), functional spinal unit height, heterotopic ossification, and adjacent segment degeneration. Heterotopic ossification was assessed using the grading system adapted from McAfee and Mehren.^{27,28} Adjacent

segment degeneration was assessed using the grading system adapted from Kellgren and Lawrence.²⁹ A team of independent radiologists (Medical Metrics, Inc., Houston, TX) made all radiographic determinations.

Primary Success Endpoint

The primary endpoint for the study was a composite definition of patient success. In order to be considered a success, a patient had to meet each of the following criteria:

- An improvement in NDI score of at least 30 points for a patient with a preoperative NDI score of 60 or greater; or an improvement of at least 50% of preoperative NDI score for patients with a preoperative score of less than 60;
- No subsequent surgical intervention at the index level(s);
- No adverse events (AEs) classified as major complications by a clinical events committee (CEC);
- Maintenance or improvement in neurologic function;
- Radiographic success.

All subsequent surgeries were collected and documented in detail consistent with previous descriptions.^{13,15,24,25} The study protocol did not specify the indications for reoperation in either treatment group. The decision for subsequent surgical intervention was determined solely by the treating surgeon and the patient's personal decision to proceed. Consistent with other analyses,^{9,11,15,18} index-level secondary surgeries were categorized when possible as a revision, removal, reoperation or supplemental fixation. Essentially, any surgery that touched the index level was considered as an index-level reoperation, even if the primary goal of surgery was to correct an adjacent level problem. Secondary operations at adjacent levels were documented as well. Thus, operations at adjacent levels only were not considered in the primary success-or-failure study endpoint. However, operations that involved both index and adjacent levels were considered in the primary success or failure study endpoint. For plate removals, if the plate was removed from the index level to extend the fusion to an adjacent level, this event was considered a removal per the study protocol and considered a failure

Fig. 1. The Mobi-C® Cervical Disc.

for the primary endpoint.

Adverse events (AEs) were defined as any clinically adverse sign, symptom, syndrome, or illness that occurred or worsened during the operative and post-operative period. AEs were assessed by a Clinical Events Committee (CEC) composed of two orthopedic surgeons and one neurosurgeon. The members of the CEC were not investigators on the study and were blinded to treatment whenever possible. Any patient with an AE that was determined by the CEC to be a major complication of the treatment was considered a study failure.

Neurological assessments were performed by the investigator using tests of sensory, reflex, and motor function. Any patient with a decrease in sensory, reflex, or motor function from preoperative status was considered a failure.

For the TDR group, radiographic success was defined as at least 2° of segmental motion in flexion-extension or no evidence of bridging bone across the disc space. Grade IV heterotopic ossification was an indication of bridging bone. For the ACDF group, radiographic success was defined as fusion of the treated level(s), less than 2° of segmental motion in flexion-extension, and evidence of bridging bone across the disc space with radiolucent lines at no more than 50% of the graft vertebral interfaces.

Statistical Methods

The primary endpoint was assessed with the hypothesis of non-inferiority of TDR versus ACDF with a 10% non-inferiority margin. Non-inferiority was tested using a 95% one-sided lower confidence bound of the difference between the investigation and the control group. A closed testing procedure was prespecified for superiority, to be tested in the event that non-inferiority was confirmed. If non-inferiority was confirmed, superiority was tested using a 95% lower confidence bound.

There were two distinct methods of outcome assessment. To evaluate the change in outcomes specifically at seven years, p-values for differences in improvement from baseline in NDI, VAS, and SF-12 scores at 84 months were calculated using repeated measures,

mixed effects ANOVA adjusted for multiplicity.

A global outcome assessment was also performed to evaluate the aggregate change in outcome over the entire seven year study period (inclusive of all of the previous time points including two year, five year, and seven year time points). Global p-values for differences in absolute NDI, VAS, and SF-12 scores between TDR and ACDF were calculated using repeated measures, mixed effects ANOVA across all post-operative time points.

Secondary surgery survival function estimates were generated using the Kaplan-Meier method, with the log-rank test to compare survival functions. Patients undergoing a removal, revision, or supplemental fixation procedure were censored at all time points after the surgery for secondary outcomes (e.g. NDI, VAS). P-values for categorical endpoints were calculated using a two-sided Fisher's exact test. Statistical analyses were performed using SAS version 9.4 (SAS Institute, Cary, NC). All patients that were discontinued (e.g. withdrawn, lost-to-follow-up, device removal) were censored at their last follow-up prior to study withdrawal. A scenario analysis was performed to determine the potential influence of discontinued patients, including last observation carried forward (best-case scenario), and all discontinued patients counted as failures (worst-case scenario analysis). Under each scenario analysis, TDR remained either superior or non-inferior to ACDF.

Results

Preoperative patient characteristics and clinical outcomes were similar between treatment groups within treatment arms (Table 2). The inclusion criteria required that patients smoke less than one pack per day, but the preoperative smoking status of each patient was not collected as part of the study protocol. However, a post-hoc survey conducted by the investigators estimated the proportion of smokers in the study to be 15.1% for ACDF patients and 18.7% for TDR patients.³⁰ At 7 years, the follow-up rate was 84.4% for the two-level TDR group, and 75.0% for the two-level ACDF group, and 80.1% for the one-level TDR group and 74.3% for the one-level ACDF group. The follow-up rates were calculated using the FDA

guidelines for orthopedic device clinical trials.³¹

Two-Level Treatment Arm

Primary Success Analysis – Two level

At 7 years, two-level TDR demonstrated superiority compared to two-level ACDF (Figure 2). The rate of success was 60.8% (104/171) in the TDR group and 34.6% (27/78) in the ACDF group with a difference of 26.2% and lower 95% confidence bound of 15.4%. Analyzing the individual components of success illustrates that the primary driver of 2-level TDR superiority was due to a significant difference in percentage of successful NDI scores (TDR 79% vs ACDF 58%), lower incidence of subsequent surgery (4.4% vs 16.2%), and lower incidence of neurological failure (6.4% vs 17.1%; Table 3). The differential success of TDR was not attributable to differences in the rate of adverse events or radiological deterioration between groups.

Patient Reported Outcomes - Two level

Two-level TDR and ACDF patients had similar pre-operative NDI scores, and NDI at all follow-ups was significantly improved from baseline for both treat-

ments though seven years. Globally, TDR patients had significantly lower NDI scores than ACDF patients ($p < 0.0001$; Figure 3) averaged across all followup periods. Specifically at the seven year followup endpoint, the TDR group also had greater improvement in NDI scores (35.6 ± 20) than the ACDF group (28.2 ± 21.7 ; $p = 0.04$) at 7 years (Table 4). Considering the recovery ratios, NDI scores improved 67% over baseline in the TDR group and 53% in the ACDF patients. For two-level patients, the most improved NDI item was Pain Intensity for ACDF (2.0 points) and Recreation for TDR (2.4 points). For

Fig. 2. Overall treatment success of two-level TDR and ACDF.

Values given are mean ± SD unless otherwise indicated.

Table 5. NDI and pain status (% of patients) at last follow-up in 2-level TDR and ACDF.

Status*	NDI			VAS Neck Pain		
	TDR	ACDF	P value†	TDR	ACDF	P value†
Improved	80.8%	70.2%	0.10	86.0%	77.7%	0.15
Not improved	16.5%	25.9%		9.0%	15.5%	
Worse	2.7%	3.8%		5.0%	6.8%	

* NDI: Improved: $\geq 15/100$ point increase from baseline. Not improved: < 15 point change (\pm) from baseline. Worse: $\leq -15/100$ point decrease from baseline.

Neck pain: Improved: $\geq 10/100$ point increase from baseline. Not improved: < 10 point change (\pm) from baseline. Worse: $\leq -10/100$ point decrease from baseline.

† Fisher's exact test.

VAS neck pain and arm pain scores, both groups improved significantly compared to baseline by six weeks and maintained the improvement averaged across all followup periods (Figure 3). TDR patients had significantly lower VAS neck pain scores than ACDF patients averaged across all followup periods ($p=0.0002$; Figure 3). At the specific 7 year followup time-point, the TDR group showed a nonsignificant trend toward more improvement in VAS neck scores (50.9 ± 30.6) than the ACDF group (44.1 ± 39 ; $p=0.21$; Table 4). At the 7 year followup endpoint, VAS neck pain improved 72% over baseline in the TDR group and 57% over baseline in the ACDF group. There was no apparent difference between TDR and ACDF with respect to VAS arm pain at the 7-year follow-up endpoint (Table 4).

The vast majority of patients demonstrated improvement in NDI in the two level cohort (80% TDR and 70.2% ACDF; Table 5) and there was a strikingly low percentage of patients who had worse NDI scores (2.7% TDR and 3.8% ACDF; $p=0.10$). Overall, the vast majority of patients demonstrated improvement in VAS neck pain in both the two level cohort (86%

TDR and 77.7% ACDF; $p=0.15$) and the single level cohort (87.5% TDR and 83.8% ACDF; $p=0.21$). Similarly, there was a strikingly low percentage of patients who had worse NDI scores in both the two level cohort (5% TDR and 6.8% ACDF) and the single level cohort (3.8% TDR and 1.3% ACDF; Table 5).

Both patient groups saw a significant improvement in SF-12 PCS/MCS scores from baseline. TDR had significantly higher postoperative SF-12 PCS scores averaged across all time points ($p=0.0003$), but SF-12 MCS scores were similar in both treatment groups (Figure 3). At the specific seven year time point, there were no statistically significant differences in SF12 PCS or MCS scores.

Table 3. Overall success and components of success for 2-level TDR and ACDF.

	TDR	ACDF	Difference
Composite success	60.8%	34.6%	26.2%*
NDI success	79.0%	58.0%	21.0%†
Subsequent Surgery	4.4%	16.2%	11.8%†
Neurologic failure	6.4%	17.1%	10.7%†
Adverse events	5.3%	8.6%	3.3%
Radiographic failure	10.1%	9.1%	1.0%

* Superiority of TDR vs. ACDF established with 95% lower confidence bound of difference $> 0\%$. † $p < 0.05$; Fisher's exact test.

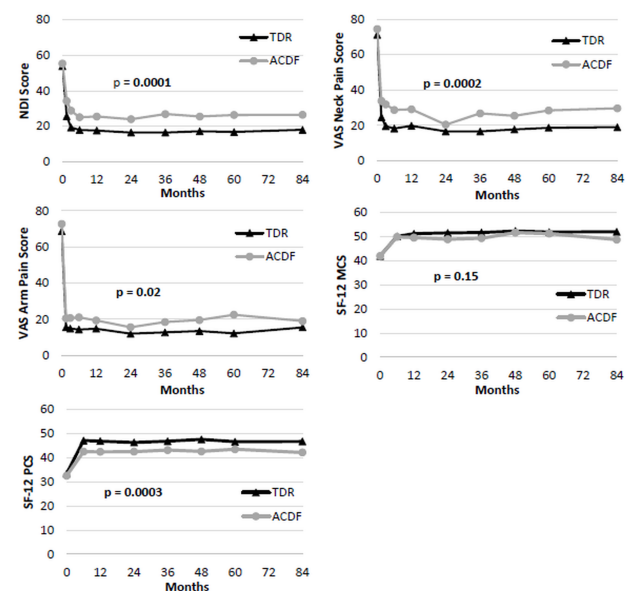

Fig. 3. Patient-reported outcomes for two-level TDR and ACDF Patients from preoperative to 7 years follow-up. P-values are from global test of the difference between TDR and ACDF patient scores, generalized across all time points. Top Left: Mean NDI scores. Top Right: Mean VAS Neck Pain scores. Middle Left: Mean VAS arm pain scores. Middle Right: Mean SF-12 MCS. Bottom Left: Mean SF-12 PCS.

Overall patient satisfaction was high in both groups with high proportions of patients in both groups describing themselves as “very satisfied” [TDR: 86.0% (160/186) vs. ACDF: 73.9% (51/69); $p = 0.039$]. However, a higher proportion TDR patients answered they would “definitely” or “probably” recommend their treatment to a friend, when compared to the ACDF group [TDR: 96.8% (179/185) vs. ACDF: 88.4% (61/69); $p = 0.025$].

Radiographic Outcomes - Two level

The TDR grouped maintained range of motion in flexion/extension and lateral bending at both treated levels (Figure 4). Both groups experienced a marginal decrease in functional spinal unit height relative to postoperative measurements at both the superior and inferior treated levels (Table 6). For 2-level TDR patients, bridging bone at either level was present in 11.1% of patients (6.5% superior level/4.7% inferior level). At 7 years, 90.9% of ACDF patients met the criteria for radiographic fusion. Both groups experienced adjacent segment degeneration. However, the ACDF group presented with double the prevalence of radiographic degeneration compared to the TDR group at both the inferior (TDR 30.3% vs ACDF 66.7%) and superior (TDR 37.5% vs ACDF 80.8%) adjacent levels, respectively (Table 6).

Safety Outcomes - Two level

CEC classified adverse events rates were also similar between groups (TDR: 5.3% (12/225), ACDF: 8.6% (9/105)). TDR patients had significantly fewer subsequent surgical interventions than ACDF patients

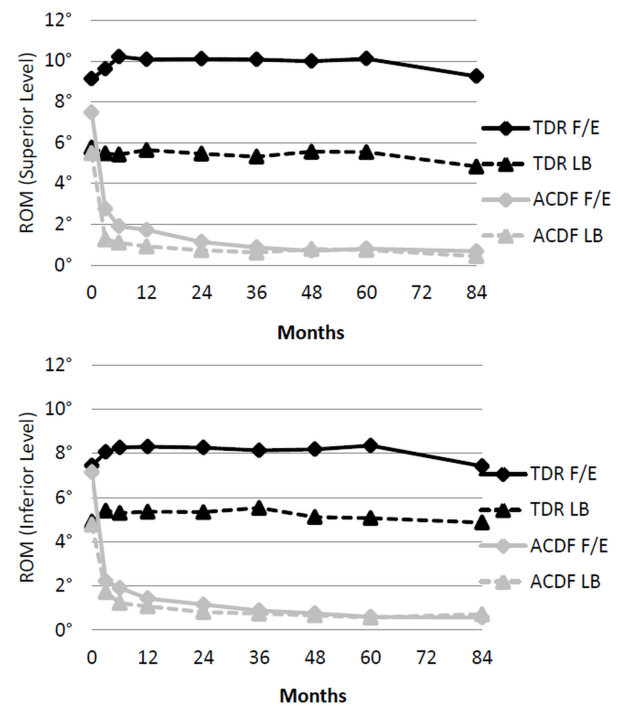

Fig. 4. Range of motion in flexion/extension (F/E) and lateral bending (LB) for two level patients. Top: Range of motion at the superior level. Bottom: Range of motion at the inferior level.

Table 4. Outcomes for 2-Level TDR and ACDF.

Study	Outcome	Treatment arm	Baseline	7 Years	Mean Δ at 7 years*	P value†	Recovery Ratio
2-Level	NDI	TDR	53.8 \pm 15.4	18.0 \pm 19.1	35.6 \pm 20.3	0.04	67%
		ACDF	55.7 \pm 15.2	26.2 \pm 22.4	28.2 \pm 21.7		53%
	VAS neck pain	TDR	71.2 \pm 20.5	19.0 \pm 27.1	50.9 \pm 30.6	0.21	72%
		ACDF	75.1 \pm 18.9	28.7 \pm 30.4	44.1 \pm 33.9		57%

did at both the treated and adjacent levels. By 7 years, subsequent surgeries at the treated level, defined as any reoperation, revision, removal, or supplemental fixation, occurred in 4.4% (10/225) of TDR patients and 16.2% (17/105) of ACDF patients ($p = 0.0008$). The TDR secondary surgeries were Removal (5), Reoperation (2), Revision (2) and Supplemental Fixation (1). Among ACDF patients, the secondary surgeries were Removal (8), Revision (4), Supplemental Fixation (3) and Reoperation (2). Discounting the plate removals at the index level (presumably to be able to access adjacent level pathology), the adjusted index level secondary surgery rate for ACDF was 10.5% for two-level. The most common reason for additional surgical intervention at the index level(s) was persistent radiculopathy and/or neck pain ($n = 7$) and pseudoarthrosis ($n = 9$), for the TDR and ACDF group, respectively. In the TDR group, there was one case of device migration that was asymptomatic, and one case of instability of the TDR due to over-preparation of the vertebral endplate that required surgical intervention. Subsequent surgeries that involved at least one adjacent level occurred in 4.4% (10/225) of TDR patients and 11.4% (12/105) of ACDF patients ($p = 0.03$). The most common reason for additional surgical intervention at an adjacent level was adjacent level disease or herniation for both the TDR ($n = 10$) and ACDF ($n = 8$) group. Kaplan-Meier survival function estimates demonstrated that TDR patients were less likely to

have subsequent surgery due to either index or adjacent level indications (Figure 5).

One-Level Treatment Arm

Primary Success Analysis - Single level

Based on the FDA required measure of composite success, there was no significant difference in overall success between TDR and ACDF in the single level cohort patients. Therefore, one-level TDR demonstrated non-inferiority compared to one-level ACDF at 7 years (Table 7; Figure 6). The rate of success was 55.2% (64/116) in the TDR group and 50.0% (25/50) in the ACDF group with a difference of 5.2% and lower 95% confidence bound of the difference of -8.7%. The main driver of the (nonsignificant) difference in success rates was a significantly lower incidence of subsequent surgery at the index level in TDR patients (TDR 3.0% vs ACDF 12.3%; Table 7).

Patient Reported Outcomes - Single level

Mean NDI scores improved significantly for both groups by six weeks, and improvement was maintained through seven years in both groups compared to baseline (Figure 7). There was no statistically significant difference between groups in global NDI in the single level cohort averaged across all time points ($p=0.11$). While the TDR group showed greater improvement at early time points, both groups demonstrated comparable mean NDI scores and mean NDI improvement from baseline (TDR 35.4 ± 20.6 vs ACDF 33.8 ± 20.2 ; $p=0.99$) at the specific seven year endpoint (Table 8). On average, NDI recovery ratios improved 67% over baseline in the TDR patients and 64% over baseline in the ACDF patients. For one-level patients, the most improved NDI item was Recreation for both ACDF (2.4 points) and TDR (2.4 points). Both the mean improvement (35 points) and the recovery ratio (67%) are strikingly similar in the one- and two-level TDR cohorts. Similarly, for VAS neck pain and arm pain scores, both groups saw a significant improvement from baseline by six weeks, which was maintained through seven years (Table 8). There was no statistically significant difference in global VAS neck pain in the single level cohort averaged across all time points. The TDR group

showed a greater level of VAS Neck Pain improvement at early time points, but this difference attenuated at the seven year endpoint, where both groups showed a similar level of pain score improvement (TDR 51.1 ± 33 vs ACDF 48.2 ± 30 ; Table 8). Overall, both groups of patients had similar VAS neck pain recovery ratios (71% TDR vs 67% ACDF). Again, the single level TDR VAS neck pain improvement (51 ± 33) and recovery ratio (71%) was strikingly similar to the two-level cohort (Table 8). There was a significantly lower global VAS arm pain in the TDR cohort averaged across all time points ($p=0.03$). However, at the specific 7 year endpoint, there was no significant difference in VAS arm pain between groups ($p=0.35$, Table 8).

In the single level cohort, the vast majority of patients demonstrated improvement in NDI (84.6% TDR and 84.8% ACDF). Similarly, there was a strikingly low percentage of patients who had worse NDI scores in the single level cohort (1.2% TDR and 2.5% ACDF; Table 9). Overall, the vast majority of patients demonstrated improvement in VAS neck pain in the single level cohort (87.5% TDR and 83.8% ACDF; $p=0.21$). Similarly, there was a strikingly low percentage of patients who had worse NDI scores in the single level cohort (3.8% TDR and 1.3% ACDF;

Table 9).

Overall, patients saw a significant improvement in SF-12 PCS/MCS scores, and both treatment groups had similar SF-12 scores through seven years (Figure 7; Table 8).

Both groups maintained a high level of patient satisfaction, calculated as the proportion of patients who answered “very satisfied” for the satisfaction questionnaire [TDR: 90.9% (120/132) vs. ACDF: 77.8% (42/54); $p = 0.028$]. A high proportion of patients from both groups answered that they would “definitely” or “probably” recommend their treatment to a friend [TDR: 96.2% (127/132) vs. ACDF: 88.9% (48/54); $p = 0.08$].

Radiographic Outcomes - Single level

Range of motion at the level treated was maintained in the TDR group with an average range of motion of $10.2 \pm 6.3^\circ$ in flexion/extension and $5.1 \pm 3.5^\circ$ in lateral bending (Figure 8). As expected, the average range of motion for the ACDF group was 1° or less in both flexion/extension and lateral bending at the level treated (Table 10). Both groups experienced a marginal decrease in functional spinal unit height relative to baseline postoperative measurements (Table 10). Bridging bone was present in 11.1% (12/108) of TDR patients. By 7 years, 95.5% of ACDF patients had achieved radiographic fusion. Both groups experienced adjacent segment degeneration, defined as at least one increase in Kellgren-Lawrence grade from baseline. However, the ACDF group demonstrated a noticeably greater prevalence of adjacent segment

Table 8. Outcomes for 1-Level TDR and ACDF.

degeneration (65.1%/63.0%) than the TDR group (40.4%/43.8%) at both the superior and inferior adjacent levels, respectively (Table 10).

Safety Outcomes - Single level

CEC classified adverse events rates were similar between treatment groups as well [TDR: 6.1% (10/164), ACDF: 3.7% (3/81)]. TDR patients had significantly fewer subsequent surgical interventions than ACDF patients did at both the treated and adjacent levels. By 7 years, subsequent surgeries (including all secondary surgeries such as index level instrumentation removals to access adjacent level pathology) at the

Fig. 8. Range of motion in flexion/extension (F/E) and lateral bending (LB) for one level patients.

	ACDF	63.0% (17/27)

Values given are mean ± SD unless otherwise indicated. * Prior to discharge from hospital.

treated level occurred in 3.0% (5/164) of TDR patients and 12.3% (10/81) of ACDF patients ($p = 0.008$). The TDR secondary surgeries were Removal (4) and Reoperation (1). The ACDF secondary surgeries were for Removal (7) or Supplemental Fixation (3). Discounting the plate removals at the index level (presumably to access adjacent level pathology), the adjusted index level secondary surgery rate for ACDF was 6.2% for one-level. The most common reason for additional surgical intervention at the index level was persistent radiculopathy and/or neck pain ($n = 3$) and pseudoarthrosis ($n = 5$), for the TDR and ACDF group, respectively. There were no cases of device malfunction, though there was one instance where the TDR device was malpositioned and required additional surgical intervention. Additionally, there was one case in which gross motion of the caudal endplate of the TDR device was noted between flexion and extension radiographs at 3 months. It was concluded that the TDR device loosened from the vertebral endplate. Thus due to over distraction of the spinal segment, possibly caused by an oversized implant; the patient had the device removed and replaced with fusion. The surgeon-investigator opined that the loosening might have occurred due to oversizing and/or over distraction of the implant. Subsequent surgeries that involved at least one adjacent level occurred in 3.7% (6/164) of TDR patients and 13.6% (11/81) of ACDF patients ($p = 0.007$). The most common reason for additional surgical intervention at an adjacent level was adjacent level disease or herniation for both the TDR ($n = 4$) and ACDF ($n = 8$) group. Kaplan-Meier survival function estimates demonstrated that TDR patients were less likely to have subsequent surgery across time (Figure 9).

Discussion

These results indicate that cervical spine surgery for properly selected patients with myelopathy or radiculopathy is tremendously effective at improving patient pain and quality of life. Overall, greater than 95% of patients (from both groups) who underwent TDR and 88% of patients who underwent ACDF were “very satisfied” at seven years. When comparing TDR to ACDF, these results add to the growing body of literature supporting the long-term outcome and decreased secondary surgery rate of TDR com-

pared to ACDF.

Although the change in disease specific outcome measures and statistical testing is of value to the scientific community, patients may struggle to understand the specific implications of this data. As one recent study reported, “interpretation of the data is very difficult or even impossible for most patients due to lack of adequate knowledge.” “From a patients perspective a total NDI score or a difference in NDI score, that is however important for scientific evaluation, is meaningless. It will not help him/her in decision-making about any treatment for neck-related problems.”³² Therefore, in this study, we have attempted to transform the outcome scores into expressions that can easily be understood by patients to help them in making a decision about their eventual treatment. Here we report that the vast majority of patients in both single and two level cohorts improved in neck disability after surgery (70.2%-80.8% of two-level surgeries and 84.6%-84.8% of single level surgeries) and neck pain (83.3%-87.5% of single level surgeries and 77.7%-86.0% of two-level surgeries).

In contrast to the conventional wisdom of “50 percent improved and 50 percent worse” outcome distribution, the percentage of patients with worse neck disability (2.5%-3.8% of two-level surgeries and 1.2%-2.5% of single level surgeries) and worse VAS neck pain (5%-6.8% of two-level and 1.3% - 3.8% of single level) was strikingly low. To further facilitate patient education and individualized treatment ap-

proaches, the data in this study are also reported in terms of recovery ratios. A higher recovery ratio implies more improvement in outcome normalized to maximal possible improvement. For instance, a patient with a preoperative NDI of 80 and a postoperative NDI of 20 would have a 75% recovery ratio. In this study, patients who underwent two-level total disc replacement experienced a mean 72% reduction in neck pain, 74% improvement in arm pain, and 67% improvement in disability relative to an idealized improvement. Similarly, patients in this study who underwent a single-level total disc replacement experienced a mean 71% reduction in neck pain, 73% improvement in arm pain, and 67% improvement in disability relative to maximal possible improvement. We believe that it is imperative that our clinical trial results be translated into lay language to aid patients, non-spine providers such as insurance medical directors, and policy makers in their decision-making.

There was a clear reduction in secondary surgery rates following TDR at long-term follow-up in both the single and two level cohorts. Index level secondary surgery rates were significantly lower in the TDR population at seven years in the single level (3.0% TDR vs 12.3% ACDF) and two level (4.4% TDR vs 16.2% ACDF) when all index level procedures (including plate removal) were included. Radiographic pseudoarthrosis was present in 9.1% of the 2-level ACDF patients and 4.5% of the single level ACDF patients who did not undergo secondary surgery by seven years. The rate of secondary surg-

Fig. 9. Kaplan-Meier survival function estimates for subsequent surgery in one-level patients. P-value based on log-rank test. Left: Subsequent surgery for index level indications. Right: Subsequent surgery at the adjacent level.

eries due to pseudoarthrosis was 8.6% for 2-level and 6.2% for one-level. Adjacent segment secondary surgery rates were also significantly lower in the TDR patients in the single level (3.7% TDR vs 13.6% ACDF) and two level (4.4% TDR vs 11.4% ACDF) patients. The difference in adjacent level secondary surgery rates is consistent with the observed increase in radiographic adjacent segment disease rates in the ACDF patients.

Our data are consistent with other Level I evidence clinical trials that have reported on the safety and efficacy of TDR with follow-up periods up to 7 years.³³ Overall, the results have been favorable for TDR, with results comparable to or better than ACDF control groups. In a 7-year study on the ProDisc-C device, Janssen et al. reported comparable results of one-level TDR compared to ACDF with respect to disease specific outcomes.⁹ Additionally, investigators observed a lower rate of subsequent surgical procedures at both the treated level and adjacent levels.⁹ Burkus et al. published similar 7-year findings on the Prestige device with comparable or better outcomes for the TDR group with almost three times fewer index and adjacent level surgeries in the disc group.¹⁸ In a 5-year study on the PCM device, Phillips et al. reported better outcomes for neck pain, similar AE rates, and lower rates of subsequent surgery and radiographic degeneration for their one-level disc group compared to ACDF controls.¹¹ Although some early studies of other discs did not report a statistically significant difference in secondary surgery rates at early time points, long-term follow-up has demonstrated that motion preservation reduces secondary surgery rates.

While several high-quality studies have validated the long-term safety and efficacy of one-level TDR, to the authors' knowledge, this study is one of two high-quality, randomized clinical trial to evaluate the long-term performance of two-level TDR. The results of other, short-term studies, while limited in quantity, are in accordance with these results presented here. In a prospective, randomized, 65-patient study of two-level TDR versus ACDF, Chen et al. demonstrated favorable outcomes for two-level TDR (Bryan), with significantly more improvement in NDI and neck pains scores over an ACDF compari-

son group at two years.³⁴

The dramatic difference seen between TDR and fusion when moving from one-level to two-levels of treatment is also noteworthy.³⁵ As discussed in the results, the outcome of TDR is remarkably similar at one and two levels. Although there previously was a statistically significant difference between single level TDR and ACDF, at long term follow-up the differences in success rate, NDI score, VAS score, and other clinical outcome measures are no longer statistically significant. While one-level treatment with TDR offered similar results in patient reported outcomes versus ACDF in the long-term, a sizeable difference in treatment effectiveness was observed between two-level TDR and ACDF. Treatment with ACDF appeared to experience diminishing returns as the number of treated levels increases, while TDR does not, or does to a much lesser extent.^{35,36} A likely explanation for this phenomenon lies in the apparent biomechanical differences between fusion and disc replacement.^{7,37,38} In accordance with this hypothesis of transfer of biomechanical stresses in multilevel disc replacement, there was a striking difference in the recovery ratios of VAS neck pain between groups. In the single level cohort, neck pain improved on average 67% relative to idealized improvement from baseline score. In the two level group, neck pain improved only 57%. Therefore, although the difference in mean VAS improvement is small (4 points on a 0-100 scale), there was a 10% difference in the recovery ratio. Additionally, there was an increase in the incidence of radiographic adjacent segment degeneration in the ACDF patients between cohorts (2-level 80.8% vs 65.1% 1-level). The observed increase in radiographic degeneration is also in accordance with the theory that there is increased mechanical stress following two level fusion.

There is no doubt that ACDF is still a highly useful and successful procedure, especially for treating symptomatic spondylosis accompanied by marked cervical instability, facet arthropathy, disc space collapse, or kyphosis. One limitation of this study was the specific inclusion and exclusion criteria for entry into the study. At the time of conception, the intention of the Mobi-C study was to enroll patients without significant conditions that could confound the

outcome of an artificial disc. Other studies have demonstrated that less than half of the patients who present to a spine surgeon's office with cervical spine complaints are candidates for a TDR based upon IDE study criteria.³⁹ Therefore, the generalizability of these results to patients outside of IDE study conditions may be limited. There may also be other variables that affect the outcome of TDR that were not captured in this report. As the understanding of TDR has improved since the conception and initiation of this study almost 10 years ago, several technical factors have been identified that may be potential confounders. For example, a retrospective analysis of the Discover disc revealed that a preoperative disk height of <3.5 mm or excessive intraoperative lordosis, (such as increasing the functional spinal unit angle by >3 degrees) was associated with a 3.5 times greater risk of not achieving the MCID in NDI ($p=0.016$).⁴⁰ Another recent study demonstrated that subtle micromotion between the implant and the vertebral endplates (less than the threshold for macro-motion and migration described as an adverse event above) might affect clinical outcome.⁴¹ Therefore, there may also be subtle surgical factors, such as height,⁴² alignment,^{43,44} or removal of the PLL,^{44,45} that may affect TDR kinematics and that limit the generalizability of the results.⁴⁴ Additionally, we acknowledge that the indications and rate of secondary surgery are somewhat subjective. One group of authors reported a higher rate of secondary surgery in ACDF patient within an IDE study than a concurrent group of ACDF patients outside of IDE study conditions.⁴⁶ The authors inferred that IDE study conditions might lead to a subtle bias towards increased rates of secondary surgery in ACDF patients who would otherwise be managed without surgery. Although we acknowledge possible bias in the subjective decision on the part of the surgeon and patient to consider a secondary surgery, we also report concordant clinical failure measured in objective parameters such as radiographic adjacent segment disease rates and clinical outcome measures. We believe it is entirely reasonable that, in a group of patients with an increased rate of radiographic degeneration and worse clinical outcomes, we would observe an increased rate of secondary surgery. Additionally, at least 47% of secondary surgeries were performed by non-investigator surgeons, which may also reduce

likelihood of investigator bias. The FDA composite success endpoint (that consists of clinical and radiographic measures) is an attempt to capture all treatment failures, including secondary surgeries or patients who have a poor outcome who choose not to undergo secondary surgery. All IDE clinical trials of TDR have used a composite success endpoint to test for non-inferiority against ACDF; however, the definition of overall success has varied among these studies.⁴⁷ The composite success endpoint used the Mobi-C trial was mandated by the FDA from the beginning of the IDE and has been reported in earlier studies.²³ At various times during this study, however, the FDA imposed alternative definitions of overall success.^{24,25} For the purposes of this study, we used the original FDA definition of success criteria. However, we acknowledge that, due to the small changes in FDA definitions of success, direct comparisons of overall success rates across studies may not be valid. Another limitation is that the study was funded by industry. Some authors perceive industry funding to induce a source of bias, although this is true for all medical device studies. Most spine device trials, particularly multicenter studies, are industry funded.⁴⁸ Additionally, authors have declared potential conflicts of interest. Another source of bias was affirmation bias or confirmation bias, although that is probably true for most medical device studies. Due to the differences in postoperative rehabilitation, it was not possible to blind patients to their treatment allocation. For treating symptomatic spondylosis in which the spine is generally stable, these data suggest that the stability provided by fusion is not worth the sacrifice in motion. With an apparent reduced risk for reoperation and adjacent segment pathologies, motion-preserving treatment with TDR seems to be an excellent alternative to ACDF, given the data presented here and in many other studies.

Conclusion

For the treatment of one- or two-level symptomatic cervical disc disease, TDR with the Mobi-C Cervical Disc is a safe procedure with excellent long-term effectiveness. Compared to an anterior fusion alternative, TDR provided a similar reduction in patient reported outcomes of pain and function while providing a lower risk for reoperation at both treated and

adjacent levels. The improvement in outcome between TDR and ACDF appears to be durable from the two-year to the seven-year follow up. The difference in clinical effectiveness of TDR versus ACDF becomes more apparent as treatment increases from one to two levels, indicating a significant benefit for TDR over ACDF for two-level procedures.

Disclosures & COI

The device manufacturer, Zimmer Biomet (formerly LDR Spine), sponsored the Mobi-C® Cervical Disc FDA IDE clinical trial. Zimmer Biomet contributed to the design and conduct of the study and provided assistance with analysis of data and manuscript review. The authors also report receiving writing or editorial assistance for this paper from Zimmer Biomet. Dr. Radcliff: unpaid consultant for 4 Web Medical; board or committee member for ACSR; paid consultant for Altus Spine; paid consultant, research support, and unpaid consultant for DePuy, a Johnson & Johnson Company; intellectual property (IP) royalties, paid consultant, and research support from Globus Medical; unpaid consultant for Zimmer Biomet; paid consultant and research support from Medtronic; other financial or material support from NEXXT Spine; other financial or material support from NuVasive; paid consultant for Orthofix, Inc.; IP royalties and paid consultant for Orthopedic Sciences, Inc.; research support from Pacira pharmaceuticals; research support from Paradigm Spine; and other financial or material support from Stryker. Dr. Davis: consultant for Zimmer Biomet and Titan Spine. Dr. Bae: patent holder for Zimmer Biomet; research support from Zimmer Biomet; paid consultant for Zimmer Biomet; receives royalties for products from NuVasive, Stryker, and Zimmer Biomet. Dr. Hisey: consultant for Zimmer Biomet, DePuy/Synthes Spine, and SAB Innovasis; patent holder for Zimmer Biomet. Dr. Nunley: direct stock ownership in Amedica, Paradigm Spine, and Spineology; has received support of non-study-related clinical or research effort from the Cervical Spine Research Society, K2M, Axiomed, Medtronic, Nutech, NuVasive, Spinal Motion, and Vertiflex; is a patent holder for K2M and Zimmer Biomet (specifically for the ROI-A anterior lumbar interbody fusion cage); is a consultant for Nutech, Amedica, K2M, and Zimmer Biomet; and has received royalties, performed speaking

and teaching arrangements, and served on the scientific advisory board of Osprey Biomedical and K2M. Dr. Hoffman: direct stock ownership in Zimmer Biomet and Nanovis. Dr. Jackson: consultant for Zimmer Biomet; has received clinical or research support for this study from Zimmer Biomet; receives royalties from Globus Medical; stock ownership in Medtronic and Johnson and Johnson. Dr. Albert: board or committee member for Scoliosis Research Society; stock or stock options from ASIP; IP royalties from Biomet; stock or stock options from Biometrix; stock or stock options from Breakaway Imaging; stock or stock options from Crosstree; IP royalties and paid consultant for DePuy, a Johnson & Johnson Company; stock or stock options from Gentis; stock or stock options from InViVo Therapeutics; stock or stock options from Invuity; publishing royalties, financial or material support from Jay Pee; editorial or governing board *Journal of Bone and Joint Surgery*(American); stock or stock options in Paradigm Spine; publishing royalties, financial or material support from Saunders/Mosby-Elsevier; editorial or governing board for *Spine*; editorial or governing board for *Spine Deformity Journal*; stock or stock options in Spinicity; publishing royalties, financial or material support from Thieme; other financial or material support from United Healthcare; and stock or stock options in Vertech. Dr. Coric: royalties, stock ownership, and consultant for Spine Wave; stock ownership in DiscGenics and Spinal Kinetics; and consultant for Medtronic, Globus Medical, Stryker, and United Healthcare; and speaking and/or teaching arrangements for Globus.
