ABSTRACT

Background: This review paper outlines recent advances in diagnostic criteria for hypermobility spectrum disorder (HSD) and its association with Ehlers-Danlos syndrome (EDS), as well as current literature on the association between joint hypermobility syndrome and lumbar back pain. We outline the optimal multidisciplinary management of lumbar back pain in the context of joint hypermobility syndrome, as well as the indications and possible side effects of surgical management of patients with these conditions.

Several studies have suggested a link between chronic low back pain and hypermobility. HSD has been described as an excessive range of motion in a joint, when accounting for patient demographics. The nomenclature surrounding symptomatic joint hypermobility has varied historically, and various groups, including most notably the international EDS consortium, have introduced new classification schemes to acknowledge the systemic effects of joint hypermobility, which were previously poorly understood.

Methods: Narrative literature review.

Results: Not applicable.

Conclusions: Lower back pain experienced in patients on the HSD-EDS spectrum is multifactorial in origin and should not be considered solely in anatomical terms. Caution has been advised in the surgical management of patients on the HSD-hEDS spectrum, particularly where the subtype is unclear. The vascular type of EDS has a particular propensity for severe bleeding complications. Rates of perioperative complications after lumbar spinal surgery in the hypermobile EDS population have been reported to be up to 50%. When hypermobility and chronic lumbar back pain coexist, we advocate management in a multidisciplinary setting involving physiotherapists, pain physicians, surgeons, and psychologists.

Lumbar Spine

Keywords: joint hypermobility syndrome, Ehlers-Danlos syndrome, lumbar back pain, joint hyperlaxity

BACKGROUND

Joint hypermobility (JH) has been described as an “excessive range of motion in a joint, when accounting for patient demographics including age, gender and ethnicity.”¹ JH may be present in an isolated joint or can be a feature of a widespread connective tissue disorder with generalized joint hypermobility and nonarticular manifestations.^{2,3}

The nomenclature surrounding symptomatic JH has varied historically. The diagnostic term *joint hypermobility syndrome* (JHS) was initially used when patients experienced symptoms associated with multijoint laxity. As our understanding of JHS evolved, there was a belief that the condition

was often indistinguishable from hypermobile Ehlers-Danlos (hEDS), and as such the 2 terms were often used interchangeably.^{4,5} In 2017, the International EDS Consortium proposed a revised EDS classification, which recognized 13 subtypes, clarified the diagnosis of hEDS, and discontinued use of the term *JHS* (Table 1; Figure 1). This consortium introduced the term *hypermobility spectrum disorder* (HSD), which was used to encompass those patients with symptoms associated with their hypermobility but not fulfilling the criteria of hEDS or any other heritable disorder of connective tissue (HDCT; Figure 2).⁵

It is estimated that 3.4% of the population have generalized joint hypermobility and associated

chronic widespread pain.^{4,5} This prevalence rivals fibromyalgia, gout, and rheumatoid arthritis.⁶ Despite its prevalence, it is underdiagnosed by physicians due to its highly variable clinical presentation and controversies regarding its etiology, nomenclature, and pathogenesis.^{7,8}

Several studies have suggested a link between chronic low back pain (cLBP) and hypermobility.^{9,10} Given the current understanding of the existence of HSD and hEDS on a continuum, we have referenced articles using both terms, as well as the historical term *JHS*. The aims of this article are to outline a new classification system for these connective tissue disorders (HSD and hEDS); to discuss the identification of these patients in clinic; and finally, to offer some guidance on the management of cLBP in patients with hEDS.

DIAGNOSIS AND SEQUELAE OF HYPERMOBILITY SYNDROMES

The diagnosis of both HSD and hEDS are diagnoses of exclusion. Patients will often give a history of subluxations and dislocations coexisting with dermatological symptoms such as extensive bruising. These are often associated with abnormal pain processing, fatigue, autonomic dysfunction, mental health symptoms, and wider visceral involvement such as uterine prolapse and abdominal hernias.^{4,5} Patients may also have a positive family history of hypermobility, but the spectrum of system involvement and severity of presentation varies widely.

Given that the history may be vague, a detailed musculoskeletal examination is key. The measurement of joint hypermobility can be supported by a number of scoring systems, the most prevalent of which is the Beighton score (Table 2).¹¹ First

Figure 1. Two-dimensional variability of joint hypermobility syndrome represented by the vertical (pathogenesis) and horizontal (etiology). Centrally, the relationships between the domains of asymptomatic joint hypermobility and Ehlers-Danlos syndrome. Generalized joint hypermobility and hypermobile Ehlers-Danlos syndrome are highlighted as the closest phenotypes, within the corresponding domains. Abbreviations: EDS, Ehlers-Danlos syndrome (various types); FGDs, functional gastrointestinal disorders; G-HSD, generalized hypermobility spectrum disorder; GJH, generalized joint hypermobility; hEDS, hypermobile Ehlers-Danlos syndrome; JH, joint hypermobility (various types); H-HSD, historical hypermobility spectrum disorder; L-HSD, localized hypermobility spectrum disorder; P-HSD, peripheral hypermobility spectrum disorder; POTS, postural orthostatic tachycardia syndrome.

Figure 2. The Hypermobility Syndromes Association (HMSA)/International Consortium with the Ehlers-Danlos Society Diagnostic Criteria (2017) representing the spectrum of presentations between hypermobility spectrum disorder and JHS/EDS hypermobility type. Abbreviations: EDS, Ehlers-Danlos syndrome; EJHS, joint hypermobility syndrome; HMSA, Hypermobility Syndromes Association.

described in 1976, it is based on the results of 9 joint examinations of only 5 areas. In the case of each examination, a positive sign is scored 1 point, with 0 points for a negative sign. The scores for all examinations are added together, with the highest possible score being 9. The threshold indicative of generalized increased joint laxity was related to age, with 6–7 in adolescents and ≥ 4 in those over 50 years of age,¹² although other cutoff values have also been applied.^{13,14}

Primarily devised for epidemiological use, as opposed to a diagnostic tool, the Beighton score provides an indication of joint laxity as part of wider syndromic assessment.¹⁵ It fails to account for the degree of joint laxity because it measures each joint in binary terms, covers only 5 areas, and does not consider rotation at any joint. However, these limitations make it clinically pragmatic. It is well validated and has been shown to have high interobserver and intraobserver reliability.¹⁶ A dermatological, cardiovascular, and abdominal examination also needs to be performed.

Table 2. Beighton 9-point scoring system.

Maneuver	Points	
	Right	Left
Ability to passively dorsiflex the 5th metacarpophalangeal joint to 90°	1	1
Ability to appose the thumb to the volar aspect of the ipsilateral forearm	1	1
Ability to hyperextend the elbow joint to beyond 10°	1	1
Ability to hyperextend the knee joint to beyond 10°	1	1
Ability to place hands flat on the floor by bending forward with knees fully extended	1	
Total	9 of 9	

On completing a detailed assessment, clinical findings should be referenced against the established set of diagnostic criteria. The new diagnosis of HSD includes most patients who were previously diagnosed with JHS or benign joint hypermobility syndrome (BJHS) and some who were previously diagnosed with hEDS. It includes all patients with hypermobility who do not fulfill the revised hEDS criteria.

For a patient to be diagnosed with hEDS, 3 specific criteria need to be fulfilled (Tables 3–5). This classification system accounts for the fact that the diagnosis of hEDS should include not only joint examination and calculation of joint hypermobility using the Beighton score, but also other clinical signs such as a Marfanoid habitus and aspects of tissue laxity, including weakness of supporting structures such as the abdominal wall (hernia) and pelvic floor (genito-uterine prolapse).

Table 3. 2017 Ehlers-Danlos syndrome classification—criteria 1, generalized joint hypermobility.

Beighton score should be calculated and one of the following selected.	
Prepubertal children and adolescents—6	
Pubertal men and women to the age of 50 y—5	
Men and women over the age of 50 y	
If Beighton score is equal to or higher than the score allocation (as above), the criteria is fulfilled. If it is 1 point below, then 2 of the following must be present to fulfill criteria 1.	
Can you now (or could you ever) place your hands flat on the floor without bending your knees?	
Can you now (or could you ever) bend your thumb to touch your forearm?	
As a child or teenager, did your shoulder or kneecap dislocate on more than one occasion?	
Do you consider yourself “double-jointed”?	

Table 4. 2017 Ehlers-Danlos syndrome classification—criteria 2.

Two or more of the following features (A, B, or C) must be present for criteria 2 to be fulfilled.

Feature A (5 must be present for feature A to be fulfilled)

- Unusually soft or velvety skin
- Mild skin hyperextensibility
- Unexplained striae distensae or rubae at the back, groins, thighs, breasts, and/or abdomen in adolescents, men, or prepubertal women without a history of significant gain or loss of body fat or weight
- Bilateral piezogenic papules of the heel
- Recurrent or multiple abdominal hernia(s)
- Atrophic scarring involving at least 2 sites and without the formation of truly papyraceous and/or hemosideric scars as seen in classical EDS
- Pelvic floor, rectal, and/or uterine prolapse in children, men, or nulliparous women without a history of morbid obesity or other known predisposing medical condition
- Dental crowding and high or narrow palate
- Arachnodactyly, as defined in 1 or more of the following: (1) positive wrist sign (Walker sign) on both sides, (2) positive thumb sign (Steinberg sign) on both sides
- Arm span to height ratio ≥ 1.05
- Mitral valve prolapse mild or greater on the basis of strict echocardiographic criteria
- Aortic root dilatation with z score > 2

Feature B

- Positive family history: 1 or more first-degree relatives independently meeting the current criteria for hEDS

Feature C (must have at least 1)

- Musculoskeletal pain in 2 or more limbs, recurring daily for at least 3 months
- Chronic, widespread pain for ≥ 3 months
- Recurrent joint dislocations or frank joint instability, in the absence of trauma

Abbreviation: hEDS, hypermobile Ehlers-Danlos syndrome.

Table 5. 2017 Ehlers-Danlos syndrome classification—criteria 3.

All of the following prerequisites MUST be met

- 1: Absence of unusual skin fragility, which should prompt consideration of other types of EDS
- 2: Exclusion of other heritable and acquired connective tissue disorders, including autoimmune rheumatologic conditions. In patients with an acquired connective tissue disorder (CTD) (eg, lupus, rheumatoid arthritis), additional diagnosis of hEDS requires meeting both features A and B of criterion 2. Feature C of criterion 2 (chronic pain and/or instability) cannot be counted toward a diagnosis of hEDS in this situation
- 3: Exclusion of alternative diagnoses that may also include joint hypermobility by means of hypotonia and/or connective tissue laxity. Alternative diagnoses and diagnostic categories include, but are not limited to, neuromuscular disorders (eg, Bethlem myopathy), other hereditary disorders of the connective tissue (eg, other types of EDS, Loeys-Dietz syndrome, Marfan syndrome), and skeletal dysplasias (eg, osteogenesis imperfecta). Exclusion of these considerations may be based upon history, physical examination, and/or molecular genetic testing, as indicated.

Abbreviations: CTD, connective tissue disease; EDS, Ehlers-Danlos syndrome; hEDS, hypermobile Ehlers-Danlos syndrome.

ASSOCIATION BETWEEN HYPERMOBILITY AND CHRONIC BACK PAIN

The presentation of cLBP in a patient on the HSD-hEDS spectrum is often unrelated to underlying structural issues, so a multifaceted approach to their clinical management is needed.¹⁷

The seminal early work on hypermobility and back pain was published in a Swedish study¹⁸ in 1995, which analyzed 606 industrial workers who were examined for these conditions (Table 6). Larsson et al¹⁸ hypothesized that hypermobility of a joint was “an asset if the joint was involved in repetitive motion and a liability if the primary role of the joint was supportive.” They identified an association between hypermobility and increased incidence of back pain and found a stronger correlation in women than men. It was speculated that this could be due to the protective effect of muscle mass in male patients.¹⁸

The study concluded that the paravertebral muscles in subjects with JHS (as defined in their

work) had to bear more load to compensate for ligamentous laxity to maintain support of their own body weight and facilitate physical activity. The increase in exertion required of the paraspinal musculature was believed to cause back pain, leading to higher disability and higher visual analog scale (VAS) scores for back pain. Another explanation for this association was that excessive joint laxity could lead to mechanical overload on intervertebral disc and facet joints, accelerating changes that may result in worsening back pain.

The Johnston County project specifically aimed to assess differences in the association between JHS and lumbar spinal symptoms stratified by race.¹⁴ The study sampled 1864 white and African American patients aged 56–76 years. A positive association between JHS (as measured by Beighton score) and back pain was identified among white patients (adjusted odds ratio [aOR]) = 1.54; 95% CI, 1.00–2.39), but a nonsignificant inverse relationship between Beighton score and back pain was identified among African-Americans (OR = 0.77; 95% CI, 0.34–1.72). Authors did not offer a definitive explanation for this marked difference between racial groups in the association between JHS and back pain.

Various studies have assessed the significance of lumbar spinal segmental hypermobility on back pain. Kim et al¹⁰ performed a retrospective case-control analysis, sampling 32 young male patients with a Beighton score ≥ 4 (JHS group), age, race,

Table 6. Published studies investigating the association between back pain/lumbar degeneration and hypermobility.

Article Title (Author, Year)	No. Patients	Variables	Results
Goode et al (2019) ¹⁹ *Including GO, GOGO, and JoCo studies	*5072	Joint hypermobility (JH) (Beighton score > 4) & incidence of back pain JH & incidence of lumbar spinal OA JH vs incidence of facet OA	pOR = 0.86 (95% CI, 0.66–1.07) pOR = 0.92 (95% CI, 0.72–1.12) pOR = 0.75 (0.55–0.94).

and body mass index matched against 32 young male patients with a Beighton score < 4 (control group). This study concluded that young men with joint hypermobility had excessive lumbar segmental motion that was associated with increased LBP, disability, and limited physical activity. One study¹⁹ that provided an interesting opposing view on the association between JHS and LBP was published in 2019. Goode et al¹⁹ showed a relationship between the ability to complete a trunk flexion maneuver and the lower incidence of back pain, suggesting a possible protective effect of ligamentous laxity and hypermobility in some cases.

Kim et al²⁰ investigated the association between JHS and lumbar disc degeneration in an MRI-based prospective cross-sectional study of 101 patients between 30 and 40 years old: 34 with joint laxity (as measured by Beighton score) and 67 without joint laxity. Both groups were matched by age and body mass index. Patients with joint laxity showed increased lumbar lordosis ($P = .004$) and increased sacral slope ($P = .003$) compared with the control group, without a significant difference in pelvic incidence ($P = .084$). On univariate analysis, a Beighton score ≥ 4 was significantly associated with a decreased risk of lumbar disc degeneration.

When managing patients with cLBP and hypermobility (both HSD and hEDS), the treating

clinician must be aware that patients may have significant pain in the absence of positive radiological findings. That the experience of LBP is more complex than purely a direct relationship with anatomical radiological changes is well accepted in the literature on cLBP. The evidence of spinal radiological changes in asymptomatic patients that worsen with age is relevant to any interpretation of radiological findings.²⁰ This second observation may explain why patients with hypermobility and cLBP may fail to respond to anatomically targeted pain management and surgical intervention.

NEUROPHYSIOLOGIC AND PSYCHIATRIC FEATURES OF HEDS

There is evidence that hEDS can be associated with central and peripheral nervous system abnormalities, such as autonomic dysfunction. Aktas et al²¹ have reported a higher incidence of carpal and tarsal tunnel syndrome in these patients. The clinician managing patients with coexisting cLBP and hEDS needs to be cognizant of the risk of peripheral neuropathies, so as not to misdiagnose them as radicular pain that is spinal in origin.

There is evidence of an association between hEDS and anxiety, with a known link between anxiety and intractable chronic pain.²² Patients with known hEDS have reported high scores for

Figure 3. Panjabi spinal stability system representing the 3 spinal subsystems.

fear of movement, as well as pain sensitization. Patients with hypermobility in Norway had higher reported health complaints and a lower understanding of their condition when compared with a control group in a limited qualitative study.²³ Clinicians should be aware that high back pain scores in some hEDS patients can be secondary to increased perception and/or reduced tolerance of pain or psychosocial factors rather than anatomical pathology.

By being mindful of the neurophysiological and psychiatric features of hEDS, the treating physician can minimize the risk of inappropriately administering targeted spinal interventions.

SPINAL BIOMECHANICS, HYPERMOBILITY, AND BACK PAIN

Panjabi and White²⁴ defined *spinal instability* as a

loss of the ability of the spine under physiological load to maintain relationships between the vertebrae in such a way that there is neither damage, nor irritation to the spinal cord or nerve roots, or development of incapacitating deformity or pain due to structural changes [see Figure 3].

Spinal stability is the result of 3 subsystems working in harmony: (1) The *passive subsystem*, consisting of the vertebrae, disc, and ligaments, which resists abnormal spinal motion at extremes of movement; (2) the *active subsystem* comprising the spinal muscles and tendons, which generate stabilizing forces; and (3) the *neural subsystem*, made up of the peripheral nerves and central nervous system that coordinate the entire stabilizing system.²⁵

In patients with HSD/hEDS, LBP could be due to a deleterious effect on the normal function of all 3 of these spinal stabilizing subsystems. This relates to the association of hEDS with abnormalities in the collagen framework of connective tissues.^{26,27} The effect this may have on proprioceptive acuity and the challenge of exercise-based management of these patients is an important consideration in rehabilitation.

This abnormality in connective tissue structure could impair the normal function of intervertebral discs and spinous ligaments (passive subsystem) and muscle and tendon function (active subsystem). The association of chronic back pain, both with and without hypermobility, with the neural subsystem through nervous system dysregulation and central sensitization has been established.^{28,29}

Nonoperative Management of Back Pain in Hypermobility

Given the complexity of the HSD-hEDS spectrum and the multifactorial pathogenesis of LBP, a multidisciplinary team approach involving pain specialists, psychologists, surgeons, and physiotherapists is essential. Coordination with a clinical geneticist may facilitate genetic counseling and subtyping if the patient displays severe systemic manifestations or evidence of marfanoid features.

Current physiotherapy techniques aim to regain function and promote self-management. This is achieved by using paced strength and conditioning programs that address proprioceptive challenges and encompass an awareness and management of muscular fatigue. Programs aim to have a strong educational component, to support acute manifestations, such as dislocations and subluxations, and to promote understanding of persistent pain.³⁰ Beliefs that may limit exercise participation have been recently explored, resulting in the incorporation of psychological therapies. Back pain scores have been shown to be improved most successfully by rehabilitation programs involving physical and psychological components, compared with exercise alone.³¹

Recommendations based on the efficacy of pain medications for use in the treatment of hypermobility are limited by lack of evidence.³² An international consortium has published recent literature on commonly used medication strategies. Paracetamol (acetaminophen, N-acetyl-p-aminophenol) and nonsteroidal anti-inflammato-

ry medications (NSAIDs) have been suggested for mild to moderate pain.^{33,34} However, the use of NSAIDs is limited due to poor tolerance secondary to comorbid gastrointestinal issues in hEDS patients. Opioids may be used for a short duration; however, there is good evidence that long-term treatment with opiates is not a viable option and may lead to central pain sensitization. Alternatives such as tricyclic antidepressants, anticonvulsants, serotonin and norepinephrine reuptake inhibitors, and other antidepressants may be used with caution, given the increased risk of dysautonomia in EDS.^{35,36} Pain management in these patients should involve pain specialists at an early stage.

Surgical and Pain Intervention Considerations

Caution has been advised in the surgical management of patients on the HSD-hEDS spectrum, particularly where the subtype is unclear. Rates of perioperative complications after lumbar spinal surgery in the hEDS population have been reported to be up to 50%. These include slow or incomplete wound healing, increased intraoperative blood loss, and surgical time.^{37,38} The vascular type of EDS has a particular propensity for severe bleeding complications. During the consent process, patients with hypermobility should be counseled regarding the increased risk of poor scar appearance, delayed wound healing, and prolonged rehabilitation.^{39–41}

Preoperatively and postoperatively, extreme care should be taken when transferring and positioning these patients, due to the risk of soft tissue abrasions and iatrogenic lacerations. It has been suggested that during an operation, soft tissue retraction should be kept to a minimum and that a multilayered approach ought to be adopted when closing the patient's incision. This reduces the risk of soft tissue injury and hematoma formation while increasing the likelihood of a cosmetically pleasing scar.¹

Postoperatively, hematology input is essential due to the increased risk of postoperative bleeding and to facilitate appropriate venous thromboembolism prophylaxis, particularly in cases of EDS in which the subtype classification is unclear. Rehabilitation may be more prolonged due to intraoperative bleeding, wound healing, and pain. Fatigue, proprioceptive deficits, coordination, and beliefs about

exercise can challenge exercise regimes, prolonging recovery.⁴²

CONCLUSIONS

Patients with hypermobility may present to the clinic with LBP as one manifestation of their condition. Consequently, clinicians treating cLBP need to be confident in identifying both HSD and hEDS and delineating the underlying pathology.

Lower back pain experienced in patients on the HSD-hEDS spectrum is multifactorial in origin and should not be considered solely in anatomical terms. The pain experience in such patients will have multiple influences including those related to fatigue and loss of proprioceptive and postural control and pain processing.

When hypermobility and cLBP coexist, we advocate management in a multidisciplinary setting involving physiotherapists, pain physicians, surgeons, and psychologists. This reflects the fact that these patients are not only at risk of cLBP but also psychological and neurological conditions such as anxiety and peripheral neuropathies. In those cases where spinal surgery is indicated, the patient must be counseled about the increased risk of perioperative complications, prolonged rehabilitation, and recovery.
